*3. Brown University School of Medicine, Providence, RI, United States.*

**Abstract:** Background: Household air pollution (HAP) from incomplete combustion of solid fuels is associated with substantial cardiopulmonary mortality, particularly in developing countries. We examined the impact of a cookstove replacement intervention on indoor fine particulate matter (PM<sub>2.5</sub>), carbon monoxide (CO) concentrations, and markers of cardiovascular and respiratory health. Methods: We enrolled 99 women (mean age: 34.4 years, SD: 7.4) from two Kenyan rural communities in a cookstove intervention study. We measured 24-hour HAP concentrations, resting blood pressure (BP) with an automated sphygmomanometer, and performed spirometry and pulse oximetry before and 1 and 6 months after stove intervention. We used robust mixed effects linear regression models to estimate post-intervention (versus pre-intervention) changes in HAP and health outcomes, adjusting for age, education, and study site. Results: Pre-intervention median (IQR) CO and PM<sub>2.5</sub> levels were 19.0 (9.0-40.8) ppm and 64.0 (36.0-127.0) µg/m<sup>3</sup>, respectively. All participants reported using wood as their primary cooking fuel, with 93% having no access to a gas cook stove and 88% having no access to electricity. Cookstove intervention was associated with 12.5 (95% CI: 8.8, 16.3) ppm lower mean CO, 23.6 (4.6, 42.7) µg/m<sup>3</sup> lower mean PM<sub>2.5</sub>, 3.9 (1.3, 6.5) mmHg lower systolic BP mmHg, 1.2% (0.8%, 1.6%) higher perfusion index, and 5.5 (3.1, 7.9) bpm lower resting pulse rate at 6 months post-intervention versus baseline. Non-significant improvements in diastolic BP, exhaled CO, carboxyhemoglobin, and peak expiratory flow were also observed. Site-specific estimates varied slightly but trended in the same direction. Conclusion: Among healthy women in two rural Kenyan communities exposed to high levels of HAP, cookstove intervention was associated with lower levels of HAP and improvements in some markers of cardiovascular health after 6 months.

#### **O04.01.20. Indoor Air Pollution and Reduced Lung Function in Biomass Exposed Women: A Cross Sectional Study in Pune District, India**

Rasmila Kawan

Abstract: Indoor air pollution especially from the use of biomass fuels, remains a potentially large global health threat. The inefficient use of such fuels in poorly ventilated conditions results in high levels of indoor air pollution, most seriously affecting women and young children. The main aim of this study was to measure and compare the lung function of the women exposed in the biomass fuels and LPG fuels and relate it to the indoor emission measured using a structured questionnaire, spirometer and filter based low volume samplers respectively. This cross-sectional comparative study was conducted among the women (aged > 18 years) living in rural villages of Pune district who were not diagnosed of chronic pulmonary diseases or any other respiratory diseases and using biomass fuels or LPG for cooking for a minimum period of 5 years or more. Data collection was done from April to June 2017 in dry season. Spirometer was performed using the portable spirometer to determine the lung function over Forced expiratory volume. The primary outcome variable was forced expiratory volume in 1 second (FEV1). Secondary outcome was chronic obstruction pulmonary disease (post bronchodilator FEV1/ Forced Vital Capacity (FVC) < 70%) as defined by the Global Initiative for Obstructive Lung Disease. Potential confounders such as age, height, weight, smoking history, occupation, educational status were considered. Preliminary results showed that the lung function of the women using Biomass fuels had comparatively reduced lung function than the LPG users . The mean PM 2.5 mass concentration in the biomass user's kitchen was higher than in the LPG user's kitchen. Black carbon amount was found higher in the biomass users than LPG users . Therefore, there is an urgent need to adopt various strategies to improve indoor air quality.

#### **O04.01.21. Personal Exposure to Household Air Pollution and Lung Function in Rural Bangladesh: A Population Based Cross-Sectional Study**

Abstract: Household Air Pollution (HAP) from biomass fuel use is associated with adverse respiratory outcomes. Assessment of individual level exposure to HAP and respiratory outcomes are scarce. We are assessing association between personal exposures to HAP with lung function parameters in a population-based Bangladesh GEOHealth study. We are measuring particulate matter <2.5 micrometers (PM<sub>2.5</sub>), carbon monoxide (CO) and black carbon (BC) using personal monitors (RTI MicroPEM and Lasker CO data logger) in non-smoking women and men (n=600) aged between 25 and 65 years using biomass fuel for cooking in rural Bangladesh. The PM<sub>2.5</sub> mass is being determined by weighing the Teflon filter that accumulates PM<sub>2.5</sub> for 24hr (48hr for a subset) in the MicroPEM. BC concentration is being determined by reflectance measurement using EEL-type Smoke Stain Reflectometer. Post bronchodilator spirometry is being conducted to measure force expiratory volume in 1st second (FEV<sub>1</sub>), force vital capacity (FVC) and their ratio (FEV<sub>1</sub>/FVC) using a spirometer (nidd EasyOne™). In this preliminary analysis of 100 women aged 40±8 years (Mean±SD), median duration of cooking with biomass was 18 years with an average daily cooking time for 2.1hr. The average 48hr personal exposure to PM<sub>2.5</sub>, CO and BC was 124±108µgm<sup>-3</sup>, 1.2±0.9ppm and 4.7±2.1µgm<sup>-3</sup> respectively. About 86% of the women were exposed to PM<sub>2.5</sub>≥50µgm<sup>-3</sup> and median exposure to PM<sub>2.5</sub> during cooking was 233µgm<sup>-3</sup>. Mean post bronchodilator FVC, FEV<sub>1</sub> and FEV<sub>1</sub>/FVC were 2.6±0.5L, 2.1±0.4L and 80±8% respectively and 9% had irreversible obstruction (FEV<sub>1</sub>/FVC<0.70). We observed an inverse relationship between exposure to PM<sub>2.5</sub>>100µgm<sup>-3</sup> and lung function parameters in adjusted models but relationships were not statistically significant. Similar relationship between exposure to BC>3µgm<sup>-3</sup> with lung function parameters were also observed. Our preliminary findings indicate that lung function was affected by HAP. We will perform further analysis with data on total sample.

Abstract: Household air pollution (HAP) resulting from solid fuel use for cooking/heating is a major problem of South Asia. In Nepal, despite HAP being a key issue there is a dearth of studies that presents a comprehensive overview of environmental factors, emissions, exposure, and health burden present. We use a multi-parameter approach to identify the changes in emission, exposure and health condition of women involved with using different types of cooking fuel. The associated environmental and socio-economic factors influencing their exposure and health were studied using a structured questionnaire. The study was conducted in 2017 summer in four villages (Simreni, Gathauli, Maggar, Jancauli) of Chitwan, Nepal. 80 women between 20-30 years of age, using four different types of cooking fuel (biomass, biogas, liquefied petroleum gas (LPG) and a mix of biogas/LPG and biomass) participated in the study. Personal and indoor exposure measurements were undertaken using established low cost sensors for particulate matter (PM), black carbon (BC) and carbon monoxide (CO). Short term physiological changes were measured using standard equipment for blood pressure, lung function, and saturated oxygen content. Exhale breathe CO was also measured as a biomarker of HAP exposure. Initial analysis indicates higher exposure to CO (ppm) during cooking with biomass ( $10.4 \pm 9.1$ ) in comparison to mixed ( $8.2 \pm 7.5$ ), biogas ( $2.7 \pm 0.3$ ) and LPG ( $1.7 \pm 0.7$ ). The exhale breathe CO was observed to be the highest in biomass users ( $6.9 \pm 3.8$ ) followed by mixed ( $6.4 \pm 2.9$ ) and almost similar in LPG ( $4.9 \pm 1.5$ ) and biogas ( $4 \pm 1.7$ ) users. FEV1/FVC ratio measured immediately after cooking did not show a strong variation with different cooking fuel users ( $85.2 \pm 7.8$ ,  $85.1 \pm 2.4$  and  $85.3 \pm 4.4$  for biomass, biogas and LPG users respectively). Preliminary results suggest changing the cooking fuel from biomass to either biogas/LPG would improve health conditions of women.

### **O04.01.23. Fine Particulate Matter Exposure from Wood-Burning Cookstoves in Relation to Augmentation Index and Blood Pressure among Honduran Women**

**Abstract:** Limited, but growing epidemiologic evidence exists for associations between household air pollution (HAP) from biomass cookstoves and risk factors for cardiovascular diseases (CVDs). We evaluated the cross-sectional association of fine particulate matter (PM<sub>2.5</sub>) exposure with augmentation index, a measure of arterial stiffness, and blood pressure among women using wood-burning cookstoves in rural Honduras. Data were collected at two baseline visits (dry and rainy season) during a randomized controlled cookstove trial among 224 female primary cooks, aged 25-55 years. Personal and kitchen 24-hour PM<sub>2.5</sub> were measured gravimetrically using AirChek XR5000 pumps and Triplex Cyclones; central augmentation index and brachial blood pressure were collected via the Sphygmocor XCEL. We evaluated the associations between PM<sub>2.5</sub> and augmentation index (both log-transformed) and blood pressure in separate mixed effects regression models adjusted for age, years of school completed, waist-hip ratio, dietary diversity score, physical activity (log-transformed), and mean kitchen temperature. Median 24-hour PM<sub>2.5</sub> concentrations were 83 (25th percentile: 51; 75th percentile: 141) µg/m<sup>3</sup> and 197 (25th percentile: 81; 75th percentile: 473) µg/m<sup>3</sup> for personal and kitchen measurements, respectively. The adjusted difference in augmentation index per 10% increase in kitchen and personal PM<sub>2.5</sub> was -0.01% (95% CI, -0.13, 0.10) and -0.05% (95% CI, -0.21, 0.10), respectively. Results for systolic and diastolic blood pressure were also consistent with a null association. We did not observe any seasonal effects on the results. These results are not consistent with existing literature supporting an association between HAP and blood pressure. Given the elevated PM<sub>2.5</sub> concentrations at baseline in this study, the results may be consistent with the hypothesized supralinear exposure-response curve between HAP and CVD that suggests weaker or no association at higher concentrations.

**Abstract:** More than one-third of world's population uses biomass fuel for cooking. Use of biomass fuel has been linked to an array of adverse health hazards including cardiovascular mortality and morbidity. As part of Bangladesh GEO Health project, we are assessing whether HAP is associated with preclinical markers of cardiovascular disease (CVD) including dysfunction in microvascular circulation (by RHI). We are measuring exposure to HAP [(PM<sub>2.5</sub>, Carbon monoxide(CO) and Black carbon(BC)] for 24 hours (48 hours for a subset of 200) among 600 healthy nonsmoker adults who use biomass fuel for cooking. Exposure to PM<sub>2.5</sub> and BC has been measured using a personal monitor, RTI MicroPEM<sup>TM</sup> that use light scattering methods and also gravimetrically with an internal filter that has been both pre and post-weighed to have the deposited pollutants concentration. Laskar CO logger is being used to measure CO. Microvascular function has been measured by forearm blood flow dilatation response to brachial artery occlusion using Reactive Hyperemia-peripheral arterial tonometry (RH-PAT), a finger plethysmographic device (EndoPAT 2000, ITAMAR) which yield RHI index. A low RHI score (<1.67) indicates impaired endothelial function. Since the recruitment is underway, we have analyzed on the first 100 participants recruited to date. Average 48 hour personal exposure to PM<sub>2.5</sub>, BC, and CO, is 124 $\mu$ g/m<sup>3</sup>(SE 11.2), 4.8  $\mu$ g/m<sup>3</sup> (SE 0.2) and 1.2 ppm (SE 0.8) respectively. Mean RHI is 1.65 (SD 0.44) in our current data which is slightly below the cutoff (1.67). RHI is inversely associated with BC (OR .94, 95% CI: .7684078, 1.154878) but not significant at 5% level. No association is found with PM and CO in a preliminary analysis. As per the preliminary analysis, BC has a negative effect on CVD, Mean PM<sub>2.5</sub> is relatively much higher than the normal allowable limit. We will present complete analysis at the meeting after completion of recruitment by June 2018.

## O04.01E. Investigating Exposures to PAHs

### **O04.01.25. Temporal Trend of Exposures to Polycyclic Aromatic Hydrocarbons and Bisphenol A during 2012-2016: A Comparison between China and the United States**

Yan Lin

Yan Lin<sup>1</sup>, Xinghua Qiu<sup>2</sup>, Yifang Zhu<sup>1</sup>

1. *Environmental Health Science, UCLA, Los Angeles, CA, United States.*

2. *Environmental Science, Peking University, Beijing, Beijing, China.*

**Abstract:** At national scales, changes in human exposures to environmental chemicals are largely driven by government's regulatory actions. Due to the inter-country variations in social, cultural, and economic conditions, the temporal trends of human exposures to chemicals are likely to be different among countries. To test this hypothesis, urine samples (n=350) were collected from four panels of summer exchange students (n=45) between University of California, Los Angeles (UCLA, in Los Angeles, United States) and Peking University (in Beijing, China) in 2012, 2014, 2015, and 2016. The urinary metabolites of two groups of environmental pollutants, namely polycyclic aromatic hydrocarbons (PAHs) and bisphenol A (BPA) were measured. In each year, exposures to PAHs and BPA were both significantly higher in Beijing than in Los Angeles ( $p < 0.05$ ). From 2012 to 2016, PAHs exposures didn't change in Los Angeles, but continuously decreased in Beijing ( $p < 0.01$ ) which was probably due to the drastic reduction in PAHs emissions from residential, commercial, and industrial sources in China. BPA exposures, by contrast, continuously decreased in Los Angeles ( $p < 0.001$ ), but didn't change in Beijing. This is likely due to extensive efforts from government and manufacturers to phase out BPA in the United States and calls for actions to regulate BPA in China. Overall, the observed temporal trends of PAHs and BPA exposures reflect the difference in pollution controlling measures between the two countries.

#### **O04.01.26. Identifying Prenatal PAH Exposure and DNA Methylation Changes in Cord Blood Using a Novel Analytic Approach**

Ya Wang

*Ya Wang<sup>2</sup>, Shuang Wang<sup>2</sup>, Kylie Wheelock<sup>1</sup>, Shuk-mei Ho<sup>3</sup>, Yuet Kin (Ricky) Leung<sup>3</sup>, Julie Herbstman<sup>1</sup>, Frederica Perera<sup>1</sup>*

*2. Biostatistics, Columbia University, New York, NY, United States.*

*3. Department of Environmental Health, University of Cincinnati, Cincinnati, OH, United States.*

Abstract: PAH are ubiquitous in the urban environment, generated by combustion processes. Ambient PAH penetrate into the indoor environment. The CCCEH cohort study in NYC, a participant in the NIH ECHO consortium, has documented adverse neurodevelopmental, metabolic, and respiratory outcomes associated with prenatal PAH exposure. We analyzed DNA methylation in N=432 cord blood samples (total white blood cells), with 168 using the 450K and 264 using the EPIC array, with 485,577 and 866,895 CpG sites, respectively. We conducted standard quality control steps where we removed CpG sites on sex chromosomes, those overlapping with SNPs or on multiple locations, and kept overlapping CpG sites covered by both arrays with gene annotations, leaving 292,310 CpG sites covering 18,830 genes. We developed a weighted epigenetic distance-based method characterizing (dis)similarity in methylation measures at multiple CpGs in a gene / genetic region between pairwise samples, with weights to up-weight signal CpGs and down-weight noise CpGs. Using similarity-based approaches, weak signals that might be filtered out in a CpG-site-level analysis could be accumulated and boost the overall power. In constructing epigenetic distances, we considered both differential methylation and variation signals (method manuscript to be submitted). We applied this method to identify genes that show methylation alterations between samples with high and low prenatal PAH exposures (dichotomized at the median 2.26 ng/m<sup>3</sup>). After accounting for cell distribution and multiple comparisons, we identified 19 significant genes (FDR < 0.05). The 19 genes include RGS18, SNORD114-5, SNORD114-31, -22, and -28, PMCH, TMEM159, TMED6, OR1D2, MOBKL2B, HBB, WDR3, C9orf119, C4orf35, SNORD114-26, TXLNB, KRTAP1-3, SLC2A8 and C20orf165. This approach shows promise for identifying potential risks and mechanistic pathways associated with low-level exposures to PAH and other pollutants, which are common among pregnant women and their babies.

#### **004.01.27. Household-Level Population Estimates and Building Setbacks near Underground Natural Gas Storage Wells in PA, OH, NY, WV, MI, and CA**

Drew Michanowicz

*Drew R. Michanowicz<sup>5</sup>, Samuel Williams<sup>1</sup>, Sebastian Rowland<sup>2</sup>, Katherine E. Konschnik<sup>3</sup>, Jonathan Buonocore<sup>5</sup>, Shaun A. Goho<sup>4</sup>, Aaron S. Bernstein<sup>4</sup>*

- 5. Environmental Health, Harvard T. H. Chan School of Public Health, Boston, MA, United States.*

Abstract: Health impacts have been reported in people living near oil and gas operations (e.g., asthma exacerbation). Towards assessing these risks, studies quantifying proximate populations generally assume an even spatial distribution of population within an administrative unit (e.g., census block). These proportion population allocation (PPA) methods can be improved by excluding non-residential land use areas (i.e. dasymetric mapping), but are still too imprecise to obtain reliable estimates of population densities at small spatial scales (e.g., 50m<sup>2</sup>). Here we present ABODE (Allocation By Occupied Domicile Estimation), a novel household-level population estimation method that combines geospatial addresses, building footprints, and U.S. Census data. We assess ABODE and PPA methods by comparing population estimates within 200m of active underground natural gas storage (UGS) wells (n = 8,963) in six U.S. states. Overall, ABODE predicts slightly higher population estimates compared to PPA (48,126 vs. 43,052); however estimation bias varied by state and by individual well. ABODE captured higher populations within 200m of UGS wells in OH, WV, and PA with increases of 6, 54, and 66% compared to the PPA method, respectively. Conversely, the ABODE method captures fewer populations in NY, MI, and CA, with decreases of 4, 7, and 26%, respectively. By explicitly identifying households near active UGS wells in the six states, we also quantify well-to-building relationships and compare to state surface setback regulations where they exist. An estimated 9.4% (840) of UGS wells across the six states have at least one building within a regulated setback distance. This results in 2,769 households, or an estimated 4,816 people, living within these states' respective setbacks (e.g., 100 - 625ft.). The spatially-resolved nature of the ABODE method provides a clear advancement from previous proximity-based methods towards understanding present and future land-use conflicts.

## **O04.01.28. Validation of Silicone Wristbands as Passive Samplers for the Assessment of Exposure to Flame Retardants and Polycyclic Aromatic Hydrocarbons**

Marta Venier

*Marta Venier<sup>1</sup>, William A. Stubbings<sup>1</sup>, Shaorui Wang<sup>1</sup>, Kevin Romanak<sup>1</sup>, Amina Salamova<sup>1</sup>, Michael Hendryx<sup>2</sup>, Victoria Arrandale<sup>3</sup>, Miriam L. Diamond<sup>4</sup>*

- 4. Dept of Earth Sciences, University of Toronto, University of Toronto, Toronto, ON, Canada.*

Abstract: Personal passive samplers are seeing increasing use as they do not require energy during deployment, they are cost-effective and less-invasive, and can represent exposures integrated over a longer time-period than active samplers. Silicone wristbands have recently been used for characterizing personal exposure to a variety of chemicals but it remains unclear what route of exposure the wristband represents. We hypothesized that wristbands integrate inhalation and dermal exposure. This study examined the relationship between exposures measured using three methods: wristband, traditional active sampler and skin wipes. Exposure of each adult participant (n=10) was measured for 72 consecutive hours. During this period each participant wore one silicone wristband, one silicone brooch/badge (PDMS) and an active personal air sampler containing a glass fiber filter followed by a PUF/XAD/PUF sandwich for 72 consecutive hours. Participants also collected hand wipes samples each time before washing their hands during the 72 hour period. Samples were analysed for 9 polycyclic aromatic hydrocarbons (PAHs) and 13 flame retardants (FRs), including novel brominated flame retardants (NFRs), polybrominated diphenyl ethers (PBDEs), and organophosphate esters (OPEs) using gas chromatography mass spectrometry. BDE-47, 99, and 209 were the most abundant among PBDEs, EHTBB, BEHTBP, and DBDPE among NFRs, TCEP, TCIPP, and TPHP among OPEs, and phenanthrene among PAHs. Preliminary results indicate that PBDEs, NFRs, OPEs, and PAHs in wristbands were in the range 0.1 to 6 ng/g band, 0.1 to 10 ng/g band, 0.1 to 200 ng/g band, and 0.1 to 20 ng/g band, respectively. Levels measured in wristbands were positively correlated with levels in hand wipes and OVS samples, confirming our hypothesis. We conclude that silicone wristbands are suitable for quantitative assessment of human exposure to a large range of chemicals simultaneously, and this exposure represents both inhalation and dermal contact.

## **O04.01.29. Critical Review: Human Health Literature Related to Unconventional Oil and Natural Gas Development**

- 8. Health Effects Institute, Boston, MA, United States.*

**Abstract:** Background Development of oil and natural gas from unconventional resources (UOGD) has expanded rapidly in the last decade, and increased public and academic interest has led to a growing body of literature about its potential health effects. This review summarizes the epidemiological evidence and what the body of literature does and does not tell us about the relationship between UOGD and health. **Methods** The Health Effects Institute's Energy Research Committee (the Committee), consisting of multidisciplinary experts from across the U.S., along with HEI staff systematically reviewed the peer-reviewed and gray epidemiologic literature published between January 2000 and March 2018 by searching several electronic databases and consulting with expert stakeholders. The Committee elected to review analytical epidemiological studies worldwide with a primary focus on UOGD exposure and human health outcomes to assess whether the health of people living in locations affected by UOGD are adversely affected by the operations. Each study was assessed in duplicate for quality and risk of bias using an approach based on guidance from the National Toxicology Program Office of Health Assessment and Translation. **Results** The epidemiologic studies report associations between UOGD and various outcomes, including perinatal effects, asthma, cancer, hospitalizations and self-report health symptoms. Study authors discuss limitations of their studies, including reliance on imprecise proxies for UOG Exposure, with many noting that causality cannot be assessed without better exposure measures. This presentation will provide the Committee's findings about the strengths and weaknesses of this body of literature. **Conclusions** This systematic, impartial literature review will be useful to regulators, scientists, and others interested in understanding what is known about potential health effects of UOGD, what knowledge gaps remain, and how important knowledge gaps could be filled with future research.

#### **O04.01.30. Bioaccessibility of Polycyclic Aromatic Hydrocarbons in Airborne Particulate Matter Assessed by Simulated Lung Fluids: A Panel Study of Different Cities in Northern China**

Suhan Wang

*Peng Gao<sup>2</sup>, Suhan Wang<sup>1</sup>, Cunrui Huang<sup>1</sup>, Jian Hang<sup>2</sup>*

*2. School of Atmospheric Sciences, Sun Yat-sen University, Guangzhou, Guangdong, China.*

**Abstract:** Background: As even slight adjustments in the estimation of airborne PM-bound PAHs bioaccessibility can significantly alter risk assessment results, convenient and reliable tools are needed to determine PAHs bioaccessibility in respiratory system. Objectives: In this study, we measured 12 priority pollutant PAHs (PAH12) and estimated the lifetime excess inhalation cancer risk using their bioaccessible concentrations after simulated lung fluids extraction. Methods: Airborne PM with  $\leq 2.5 \mu\text{m}$  aerodynamic diameter (PM<sub>2.5</sub>) samples were collected from four typical cities in northeast China during the heating periods. Artificial lysosomal fluid (ALF) and Gamble's solution were used to determine PM<sub>2.5</sub>-bound bioaccessible PAH12 to calculate associated lifetime excess inhalation cancer risk by employing point-estimate approach based on relative potency factors. Results: The numbers of lifetime excess cancer cases owing to PAH12 exposure (total concentration) were 43-440 (provincial central city), 42-261 (energy mining city), 17-109 (forest city), and 20-70 (agricultural city) per million people, which corresponded to 88.81% and 94.15%, 89.12% and 96.48%, 87.49% and 89.40%, and 83.76% and 90.60% decrease in the estimated inhalation cancer risk considering bioaccessibility following 24-h Gamble's solution and ALF extraction, respectively. Benzo[k]floranthene (BkF), dibenz[a,h]anthracene (DahA) and benzo[a]pyrene (BaP) were the most bioaccessible PAH12 in the PM<sub>2.5</sub> samples after Gamble's solution extraction and were commonly found in all the cities studied. Conclusions: PAH12 concentrations widely varied across different cities affected by various PM<sub>2.5</sub> emission sources. Based on the point-estimate approach, short-term predictions of pulmonary toxicity caused by airborne PM might be underestimated if the bioaccessibility of PM<sub>2.5</sub>-bound PAH12 are not fully evaluated. Dibenz[a,h]anthracene (DahA) is a significant contributor to the estimated overall inhalation cancer risk.

## O04.01F. New Methods and Novel Matrices in Chemical Monitoring

### O04.01.31. Method Development and Validation of Dried Blood Spots as a Tool for Mercury Exposure Assessment

Andrea Santa-Rios

*Andrea Santa-Rios<sup>1</sup>, Benjamin Barst<sup>1</sup>, Nil Basu<sup>1</sup>*

Abstract: Dried blood spots (DBS) provide a minimally invasive collection method with potential to be used as a field-based research tool for exposure to environmental contaminants such as mercury (Hg). Even though previous studies provided novel techniques to measure Total Mercury (THg) and Methylmercury (MeHg) in residual DBS from newborn screening programs, a range of limitations remains including challenges with detection limit, lack of mercury speciation, and validation with paired DBS-Blood samples collected under laboratory conditions. This study follows our previous work on the matter and specifically evaluates the suitability of DBS to assess methylmercury (MeHg) and THg exposure in human and fish blood samples. It focuses on paired DBS-blood samples from venous and capillary sources of 49 human volunteers, and 10 fish (Arctic Char) samples. Paired DBS-blood, reference material and venous blood from one volunteer, was used to develop the analytical method. We used a GC-CVAFS to analyze MeHg and a Dual-Stage Gold Preconcentration for THg. Method development results based on EPA1630 guidelines, wet spikes and the use of blood reference materials showed that the measurement of MeHg in whole blood and DBS was both accurate (95-107%) and precise (2-11%). Initial results showed a high correlation for DBS-blood ( $r^2=0.83$ ) for MeHg (average  $0.96 \pm 0.73 \mu\text{g/L}$ ) for human samples, as well as for DBS-blood fish samples MeHg ( $r^2=0.94$ ), (average  $919.46 \pm 492.97 \mu\text{g/L}$ ). When coupled with other recent work in this area, there is growing confidence in the use of DBS samples to measure MeHg exposure.

## **O04.01.32. Calibration and Validation of X-Ray Fluorescence Measurements for Non-Destructive Metal Exposure Assessment of Toenail Clippings from Nigeria**

Abstract: Environmental exposure to metals has been shown to adversely affect neurologic health, cardiovascular health, and almost every system in the body. Exposure to metals has been tracked primarily using blood, which can have drawbacks as a biomarker when considering biologic half-life, collection, and storage. Toenails, which capture a longer exposure period, can be collected non-invasively, and stored at room temperature, could be much easier and more cost effective for large-scale population studies. Inductively coupled plasma mass spectrometry (ICP-MS) is typically used for analysis of toenail metal concentrations, but x-ray fluorescence (XRF) has many advantages in versatility and cost effectiveness over ICP-MS. This study compared toenail metal measurements made with XRF against ICP-MS among toenail samples collected from 20 adults in Nigeria. To do this we developed a novel calibration method that allows for correction of XRF measurements for toenail weight and thickness to accurately use XRF measurements of toenail clippings to quantify metal concentrations. We demonstrate the validity of this method in comparison to typical ICP-MS methods by comparing toenails collected from a community living in Nigeria. We found that toenail weight (correlation  $R=0.84$  between spectral estimates of weight and actual weight) and thickness (correlation  $R=0.99$  between spectral estimates of thickness and actual thickness) can be corrected for using a new calibration technique with XRF. XRF measurements of toenail Mn are comparable to ICP-MS ( $R=0.91$ ). XRF can be used effectively to quantify metals to part per million with typical XRF equipment or down to part per billion with more powerful equipment. Finally, we show that individuals living in this polluted community have much higher levels of metal exposures than typical in occupationally exposed groups.

### **O04.01.33. Moss Biomonitoring as an Alternative to Assess Exposure to Atmospheric Metals in Environmental Epidemiology: The Example of the Bramm Network and the Constances Cohort**

4. U 1168, Inserm, Villejuif, France.

**Abstract:** Background/Aim Very limited data on atmospheric metals are available nationwide with conventional devices for epidemiological research. The moss biomonitoring approach - based on the ability of mosses to proxy levels of atmospheric metals - offers an alternative. Our objective is to assess the feasibility to assign atmospheric metals exposure estimates at home addresses, using moss biomonitoring, in a large general population-based epidemiological cohort. Methods Framed by BRAMM, the French network of moss biomonitoring, mosses were surveyed for their content in 13 metals including Cd, Hg and Pb in 1996, 2000, 2006 and 2011 in 449-559 rural forest sites. After sample preparation and chemical analyses, data were interpolated by kriging to produce 2x2 km maps, from which we extracted levels of atmospheric metals at the residential address of the expected 40,000 Constances's participants living in low and moderate population density areas. Results Based on our experience in another French cohort, we expect to obtain a high spatial and temporal variability of exposure for all metals (e.g. 38 to 139 ng.g-1 for Hg, or 1.8 to 49.8 mg.g-1 for Pb). Exposures to most atmospheric metals followed gradients of population density and showed higher concentrations in industrial regions, such as the Parisian region, the North or the Rhone valley even if such data do not seem suitable for urban areas due to the characteristics of moss collection. Conclusion Moss biomonitoring is a convincing tool to assess exposure to atmospheric metals, at least in non-urban areas, and can be easily associated to epidemiological data. Two campaigns in Paris and Lyon - the main French cities - are planned to collect and use moss biomonitoring in urban areas to complete our dataset.

#### **O04.01.34. Comparison and Agreement between Venous and Capillary Blood for the Analysis of Trace Elements**

Veronica Rodriguez Saldana

*Veronica Rodriguez Saldana<sup>1</sup>, Nil Basu<sup>1</sup>, Andrea Santa-Rios<sup>1</sup>*

*1. NATURAL RESOURCE SCIENCES , MCGILL UNIVERSITY , MONTREAL, QC, Canada.*

Abstract: The use of capillary blood has many advantages over traditional venipuncture, and it has been proposed as an alternative to the use of venous blood in many fields. Since capillary blood is not identical to venous blood, there is a need to validate that both types of blood yield quality results in different applications. The aim of this study was to evaluate the agreement between capillary and venous blood for trace elements assessment and several hematological parameters. As, Cd, Ni, and Pb were determined in capillary and venous samples by Inductively Coupled Plasma Mass Spectrometry (ICP-MS) from 49 students (ages 18-36 years). Descriptive statistics and quality control parameters were calculated to review the data. The White Blood Cells (WBC) and Red Blood Cells (RBC) counts, the Hematocrit (Ht) %, and the Hemoglobin (Hb) levels were also analyzed. The precision of the method was between 6.1-15.2% for As, Cd, and Pb, while the accuracy was between 97.8-126.2% for the same elements. Ni concentrations remained below the Limits of Detection in 38% of the venous blood samples, affecting the relationship determination between the two types of blood. The results demonstrated high significant relationships for the elements of As ( $r^2= 0.866$ ), Cd ( $r^2= 0.667$ ), and Pb ( $r^2= 0.966$ ) between venous and capillary blood. The hematological parameters were highly similar. RBC and WBC counts in capillary blood were 4.67  $10^{12}/L$  and 6.70  $10^9/L$ , and 4.76  $10^{12}/L$  and 6.55  $10^9/L$  for venous blood, respectively. The Ht and Hb levels for capillary blood were 40.3% and 13.76 g/dL, and 41.2% and 13.87 g/dL for venous blood. The agreement between venous and capillary blood was determined by constructing Bland-Altman plots. The mean differences were 0.073, -0.088, and -0.38 for As, Cd, and Pb. These results demonstrate the capacity of capillary blood to be used as an alternative biomarker and its potential to be used in cost-effective methods for exposure assessment.

**O04.01.35. Nutrition Transition and Total Nail Selenium in the Peruvian Amazon in the IMAS Study (Investigacion De Migracion, Ambiente, Y Salud)**

Stacy Pettigrew

Abstract: Road development has been a major driver of the transition from traditional to calorie-dense processed 'Western' diets in lower and middle income countries. The paving of the Inter-oceanic Highway (IOH) brought rapid development to the Madre de Dios (MDD) region in the Peruvian Amazon. As traditional foods such as Brazil nuts and fish are high in selenium, we hypothesized that nail selenium may be an appropriate biomarker to measure the nutrition transition. To test this hypothesis, in 2014 we collected household surveys from 310 households in 46 communities along the IOH and nails from 418 adults. Principal component analysis of consumption frequency of 26 food items identified a Western diet factor, and we calculated household Western diet weighted sum factor scores. Diet score means were mapped into a 10 km buffer around the IOH. Generalized estimating equations (GEE) assessed the effect of this score on individual nail selenium. GEE's also assessed the influence of each food on nail selenium in urban and rural localities. Sharp differences in nail selenium were observed between urban and rural communities in an area dominated by subsistence agriculture, and higher rates of dietary transition in areas dominated by small scale artisanal gold mining and population influxes. Urban/rural status modified the effect of Western diet on nail selenium: we estimate the total nail selenium of an urban, 47 year-old (mean-aged) non-smoker would decrease 23 ng/g per unit increase in Western diet score, while rural counterparts would experience a 6 ng/g increase in selenium. Chicken, a non-traditional food, was positively associated with selenium in the rural stratum only. It is possible that chickens consumed in rural areas are raised in the household and exposed to selenium-rich local soils and food scraps. We conclude that total nail selenium is not an appropriate biomarker for stage of dietary transition in the primarily rural settlements in MDD.

#### **004.01.36. Silicone Cat Tags Detect Feline Flame Retardant Exposures**

Abstract: Since the first clinical diagnosis in 1979, the prevalence of feline hyperthyroidism in the United States has increased from 1 in 300 to 1 in 10 domesticated geriatric cats. Similar prevalence statistics are reported worldwide. Although histologically similar to human toxic nodular goiter, the underlying causes of feline hyperthyroidism remain unknown. There is some evidence that exposure to endocrine-disrupting compounds with thyroid targets may contribute to the development of feline hyperthyroidism and toxic nodular goiter. This includes exposures to brominated flame retardants (FRs), such as polybrominated diphenyl ethers (PBDEs). FR exposure routes (e.g. inhalation) are the same between cats and humans, such that cats can be used as sentinels for human exposures. In this study, silicone passive sampling devices, or cat tags, quantitatively assessed the bioavailable fraction of household FRs. Participating cats wore a cat tag for 7 days, and targeted analysis by gas chromatography mass spectrometry included 41 legacy and current FRs. Preliminary data indicated that 3 non-hyperthyroid cat tags detected a total of 11 PBDEs and organophosphate ethers. Tris(2-chloroisopropyl)phosphate (TCPP), triphenyl phosphate, and BDE-47 were detected above the limit of quantitation in all 3 cat tags. TCPP was detected at the highest concentration in each tag, ranging from 1.35 to 32.3 ng/g cat tag. This study provides proof-of-concept data for the use of silicone cat tags with companion animals and demonstrates that cat tags can compare FR concentrations in homes of hyperthyroid and non-hyperthyroid cats.

## O04.01G. Noise Effects 2

### **O04.01.37. Long-Term Residential Exposure to Environmental Noise and Cardiovascular Disease Onset: A Population-Based Cohort Study**

Larisa Yankoty

**Abstract:** Introduction: Cardiovascular effects of environmental noise are a growing concern. However, the evidence remains largely limited to the association between road traffic noise and hypertension and ischemic diseases especially myocardial infarction (MI). Objective: To examine associations between long-term residential exposure to total environmental noise and the onset of cardiovascular MI and strokes in adults of the Island of Montreal. Methods: An open cohort of 1,087,806 adults aged  $\geq 45$  years, free of MI and strokes before entering the cohort was created for the years 2000 to 2014 with the Quebec Integrated Chronic Disease Surveillance System, a systematic surveillance system from the second most populous province in Canada starting in 1996. The exposure to total environmental noise (LAeq24h) at cohort entry was estimated with a Land Use Regression (LUR) model. Onsets of MI and strokes were based on one hospital admission. Cox models were used to estimate associations. Results: We found positive associations between LAeq24h estimated and the occurrence of MI and strokes; hazard ratios adjusted for age, sex, year of entry, social and material deprivation indexes and traffic-related air pollutant (nitrogen dioxide) were respectively 1.10 (95% CI: 1.07-1.13) and 1.06 (95% CI: 1.03-1.09) per 10 dBA. Conclusion: These results suggest that total environmental noise is associated with the onset of MI and strokes. Future work should clarify if associations vary by noise sources, and if pre-existing diseases (e.g. hypertension) mediate such effects.

## **O04.01.38. Time-Varying Aircraft Noise Exposure and Incident Hypertension in the Nurses' Health Study**

**Abstract:** Background: Aircraft noise is of primary concern for communities living near airports. There is accumulating evidence of a relationship between aircraft noise and hypertension. However, most studies are cross-sectional or case-control, with limited numbers of prospective cohort studies and none in the U.S. This study aims to evaluate the association between long-term aircraft noise exposure and hypertension among participants in a large U.S. prospective cohort, the Nurses' Health Study (NHS). Methods: Day-night average sound levels (DNL) 45-75 dB were modeled for 90 airports in the U.S. for 1995-2015 in 5-year intervals using the Aviation Environmental Design Tool and were linked to geocoded addresses of participants in NHS. We performed time-varying Cox proportional hazards models for hypertension incidence to estimate hazard ratios (HRs) for each 1 dB increase in current DNL, cumulative average DNL, and indicators for current DNL >45 dB (lowest dB considered "exposed") and >55 dB, while adjusting for individual risk factors for hypertension, area-level socioeconomic status, and air pollution. Results: Among the 63,600 NHS participants free of hypertension in 1994, 28,286 new hypertension cases were observed by 2008. In each year, ~10% of the cohort were exposed to DNL levels >45 dB. In multivariable models, current and cumulative average DNL were not associated with hypertension incidence, but current exposure to >45 dB (HR=1.04; 95% CI: 0.99, 1.09) or >55 dB (HR=1.03; 95% CI: 0.89, 1.18) were associated with a suggestive increased risk. Conclusions: To our knowledge, this is the first study to evaluate the association between aircraft noise exposure and the risk of hypertension in a nationwide large prospective cohort study in the U.S. We will be investigating the noise-hypertension relationship in two additional cohorts, NHS II and the Health Professionals Follow-up Study, specifically examining the effect of nighttime aircraft noise exposure.

**Abstract:** Background: Exposure to noise has been linked to cardiovascular disease risk factors, such as elevated blood pressure and glucose dysregulation. However, epidemiologic evidence linking road traffic noise and cardiovascular disease and its risk factors remains scarce in North America. We assessed associations between road traffic noise and the incidence of diabetes and hypertension in Toronto, Canada, which is the fourth largest city in North America. Methods: We conducted a population-based cohort study of ~1 million individuals, who were aged 35-100 years and long-term residents of Toronto. Noise levels were derived using SoundPLAN Acoustics software as equivalent A-weighted sound pressure level from traffic for nighttime (LAeqNight) and 24-hour day (LAeq24h). Three-year average levels of noise were assigned to subjects' annual residential postal codes. To estimate the association between noise and outcomes, we used random-effect Cox proportional hazards models adjusting for personal and area-level characteristics. We conducted sensitivity analyses, including further adjusting for comorbidities and air pollution (ultrafine particles and nitrogen dioxide). We also fitted three-level categorical variables of noise by 5 dBA increments ( $\leq 45$  dBA and  $\leq 55$  dBA as the reference levels for LAeqNight and LAeq24h, respectively). Results: From 2001 to 2015, each interquartile range increase in LAeqNight (10.0 dBA) was associated with the incidence of diabetes (HR 1.08; 95% CI: 1.07-1.09) and hypertension (HR 1.02; 95% CI: 1.01-1.03). We found similar results with LAeq24h. These results were robust to all sensitivity analyses conducted. For diabetes, when considering noise exposure as a categorical variable, exposure to the highest levels of LAeqNight and LAeq24h was associated with HRs of 1.15 and 1.12, respectively, compared to the lowest levels. Conclusions: Exposure to road traffic noise was associated with increased incidence of diabetes and hypertension in Toronto.

## **004.01.40. Long-Term Transportation Noise Exposure and Incidence of Ischemic Heart Disease and Stroke**

**Abstract:** Background Exposure to transportation noise is widespread and has been suggested as a risk factor for cardiovascular disease. However, the evidence from longitudinal studies on ischemic heart disease (IHD) and stroke is limited. This cohort study aimed to estimate the association between exposure to noise from road traffic, railways or aircraft and incidence of IHD and stroke. **Methods** We assessed individual long-term exposure to road traffic, railway and aircraft noise based on residential histories in a cohort of 20,012 individuals. The National Patient and Cause-of-Death Registers were used to define IHD and stroke events. Extensive information on potential confounders was available from questionnaires and registers. We computed Hazard Ratios (HR) using Cox proportional hazards regression to assess associations between noise exposure and IHD. **Results** The study base of 245,000 person-years generated 1,363 and 902 incident events of IHD and stroke, respectively. We observed a particularly high risk of IHD in those exposed to all three transportation noise sources at  $\geq 45$  dB Lden, with a HR of 1.57(95%CI 1.06-2.32), and a similar tendency for stroke (HR 1.42; 95%CI 0.87-2.32). While no associations were observed between noise exposure from any of the sources and incidence of IHD or stroke, there were associations between road traffic and aircraft noise exposure 1-5 years prior to the event and IHD incidence in women, with HR of 1.11(95%CI 1.00-1.22) and 1.25 (95%CI 1.09-1.44) per 10 dB Lden, respectively. On the other hand, a decreased risk of IHD was seen for men in relation to road traffic noise exposure (HR 0.86; 95%CI 0.79-0.94 per 10 dB). **Conclusion** No overall associations were observed between noise exposure from different transportation noise sources and incidence of IHD or stroke. However, there appeared to be an increased risk of IHD in women exposed to road traffic or aircraft noise as well as in those exposed to multiple sources of transportation noise.

#### **O04.01.41. Short-Term Nighttime Wind Turbine Noise and Cardiovascular Events: A Nationwide Case-Crossover Study from Denmark**

Aslak Harbo Poulsen

*Aslak Harbo Poulsen<sup>1</sup>, Mette Sorensen<sup>1</sup>*

*1. Danish Cancer Society Research Center, Copenhagen, Denmark.*

**Abstract:** The number of people exposed to wind turbine noise (WTN) is increasing. WTN is reported as more annoying than traffic noise at similar levels. Long-term exposure to traffic noise has consistently been associated with cardiovascular disease. Effects of short-term exposure are much less investigated due to little day-to-day variation of e.g. road traffic noise. WTN varies considerably allowing investigation of short-term effects of WTN on cardiovascular events. **METHODS AND RESULTS:** We identified all hospitalisations and deaths from stroke (16,913 cases) and myocardial infarction (MI) (17,559 cases) among Danes exposed to WTN between 1982 and 2013. We applied a time-stratified, case-crossover design. Using detailed data on wind turbine type and hourly wind data at each wind turbine, we simulated mean nighttime outdoor (10-10,000 Hz) and nighttime low frequency (LF) indoor WTN (10-160 Hz) over the 4 days preceding diagnosis and reference days. For indoor LF WTN between 10 and 15 dB(A) and above 15 dB(A), odds ratios (ORs) for MI were 1.27 (95% confidence interval (CI): 0.97-1.67; cases = 198) and 1.62 (95% CI: 0.76-3.45; cases = 21), respectively, when compared to indoor LF WTN below 5 dB(A). For stroke, corresponding ORs were 1.17 (95% CI: 0.95-1.69; cases = 166) and 2.30 (95% CI: 0.96-5.50; cases = 15). The elevated ORs above 15 dB(A) persisted across sensitivity analyses. When looking at specific lag times, noise exposure one day before MI events and three days before stroke events were associated with the highest ORs. For outdoor WTN at night, we observed both increased and decreased risk estimates. **CONCLUSION:** This study did not provide conclusive evidence of an association between WTN and MI or stroke. It does however suggest that indoor LF WTN at night may trigger cardiovascular events, whereas these events seemed largely unaffected by nighttime outdoor WTN. These findings need reproduction, as they were based on few cases and may be due to chance.

#### **004.01.42. Influence of Exposure Definition on the Association between Transportation Noise and Myocardial Infarction Mortality**

Danielle Vienneau

*Danielle M. Vienneau<sup>1</sup>, Harris Héritier<sup>1</sup>, Maria Foraster<sup>1</sup>, Ikenna C. Eze<sup>1</sup>, Emmanuel Schaffner<sup>1</sup>, Reto Pieren<sup>2</sup>, Christian Cajochen<sup>3</sup>, Jean Marc Wunderli<sup>2</sup>, Nicole Probst-Hensch<sup>1</sup>, Martin Röösli<sup>1</sup>*

- 2. Empa, Laboratory for Acoustics/Noise control, Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland.*
- 3. Centre for Chronobiology, Psychiatric Hospital of the University of Basel, Basel, Switzerland.*

**Abstract:** Epidemiological research on transportation noise uses different exposure assessment strategies including regulatory noise grids or façade point (FP) estimates, with or without knowledge of the residential floor (3rd dimension). FP estimates may further relate to the maximum ("loudest") or minimum ("quiet") exposed dwelling façade. We compared associations between noise exposure and myocardial infarction (MI) mortality considering: FPs vs. noise grids, different assumptions about residential floor, and different spatial scales. Using sonBASE and residential geocodes, we assigned Lden (road and railway noise from FPs) to the 4.41mil adults in the Swiss National Cohort for the: matching residential floor (reference), middle floor, and first floor. We tested spatial scale by calculating mean Lden for each participant using all first floor FPs (or all 10m grid cells) within 50-500m buffers. For the follow-up 2000-2008, we investigated the influence of exposure definition on the association between noise and MI mortality by multipollutant Cox regression models adjusted for socio-demographic confounders and NO<sub>2</sub>. Models using the loudest FPs were robust to assumptions about residential floor. Hazard Ratios (HR) per IQR (dB) were: 1.05 (1.02;1.07) road, and 1.03 (1.01;1.05) railway. Using quiet FPs attenuated the HR for road but not for railway noise. Different patterns were apparent for buffers vs. grids depending on source. HRs for all railway buffers were similar to the reference, while the pattern for road was more erratic with largest attenuation in the 500m buffer. Using grids averaged at different spatial scales generally attenuated the HRs regardless of source. The association between road traffic noise and MI mortality was more sensitive to changes in exposure definition than for railway noise. For both sources, spatial scale seemed more important than residential floor. The use of noise maps to represent residential exposure may underestimate the health effects.

Abstract: It has been suggested that populations with a "stressed" thyroid system may be vulnerable to perfluoroalkyl acid (PFAA) exposure (1). We investigated associations between serum PFAA and thyroid hormone (TH) levels (TSH, free T4, free T3) in 10-12 year old children (N=181), and if associations differed according to iodine intake (urinary iodine). PFAAs (12 homologues) and THs were measured in serum by LC/MS/MS and by standard clinical methods, respectively, and urinary iodine by using a modified Sandell-Kolthoff method. Child sex, BMI, nursing, maternal birth country, parental education, number of older siblings, passive smoking, and urine iodine were covariates in multiple linear regressions. Participants were stratified into a low iodine group (urine iodine concentrations (1). Webster GM, et al. 2016. Environ Health Perspect 124, 935-942.

**Abstract:** Background: Prenatal exposure to per- and polyfluoroalkyl substances (PFASs) may disrupt maternal and neonatal thyroid function, which is critical for growth and neurodevelopment. Objectives: To examine associations of prenatal exposure to multiple PFASs with maternal and neonatal thyroid function. Methods: We studied 732 pregnant women and 480 neonates in Project Viva, a longitudinal pre-birth cohort in Boston, MA. We quantified six PFASs including perfluorooctanoate (PFOA) and perfluorooctane sulfonate (PFOS), and maternal thyroid hormones [thyroxine (T4), Free T4 Index (FT4I), thyroid stimulating hormone (TSH)] in plasma collected at a median 9.6 weeks gestation and neonatal T4 levels from post-partum heel sticks. We estimated associations of concentrations of single PFASs with thyroid hormone levels using covariate-adjusted linear regression models and assessed effects of exposure to multiple PFASs using multi-pollutant regression models. Results: PFASs were moderately to strongly correlated (rs: 0.19-0.74). In single-pollutant models, PFASs were not associated with maternal T4 or TSH, but PFOA, PFOS, perfluorohexane sulfonate (PFHxS), and 2-(N-methyl-perfluorooctane sulfonamido) acetate were inversely associated with maternal FT4I [e.g., -1.87% (95% CI: -3.40, -0.31) per interquartile (IQR) increase in PFOA]. Prenatal PFOS, PFOA, and PFHxS were inversely associated with T4 levels in male neonates [e.g. PFHxS, -0.46 µg/dL (95% CI: -0.83, -0.10)]. In multi-pollutant models, PFOA was suggestively inversely associated with maternal FT4I [-1.62% (-3.77, 0.57)]; in neonatal models, PFHxS [-0.36 (-0.75, 0.03)] and PFOA [-0.70 (-1.79, 0.37)] were suggestively inversely associated with T4 levels in males. Conclusions: Prenatal exposure to PFASs was inversely associated with maternal FT4I and T4 in male neonates, with evidence for confounding by PFAS coexposure. These results support the hypothesis that exposure to PFASs may influence maternal and neonatal thyroid function.

Abstract: Perfluoroalkyl substances (PFAS) are persistent chemicals often used in the production of consumer goods. Exposure to PFAS are associated with greater adiposity in children and adults, but the association of PFAS with gestational weight gain (GWG) has not been well studied. We quantified perfluorooctanoic acid (PFOA), perfluorooctane sulfonic acid (PFOS), perfluorohexane sulfonic acid (PFHxS), and perfluorononanoic acid (PFNA) concentrations in serum at 18±5 weeks' gestation for 279 women enrolled in a prospective pregnancy cohort (2003-2006, Cincinnati, Ohio) using mass spectrometry. We abstracted weight from medical records to calculate GWG from early pregnancy to delivery and rate of weight gain (GWR) in the 2nd and 3rd trimesters. We used multivariable linear regression to assess associations of GWG and GWR with individual PFAS, adjusted for relevant confounders and weeks' gestation at blood draw. We investigated effect measure modification (EMM) by pre-pregnancy BMI <25 kg/m<sup>2</sup> vs. ≥25 kg/m<sup>2</sup>, and used weighted-quantile-sum (WQS) regression to create a PFAS index to examine the combined effect of the four PFAS. Each 2-fold increase in serum PFOA, PFOS, and PFNA was associated with small and statistically non-significant increases in GWG (range 0.3-0.8 lbs) and GWR (range 0.03-0.06 lbs/week). The association of PFNA with GWG was stronger among women with BMI ≥25 kg/m<sup>2</sup> (β=2 lbs; 95% CI:-2-6) than among those with BMI <25 kg/m<sup>2</sup> (β=-0.5 lbs; 95% CI:-3-2; p-EMM=0.06). Among all women, the PFAS index was positively associated with GWG (WQS β=0.3 lbs; 95% CI: -1.0-1.5) and GWR (WQS β=0.02 lbs/week; 95% CI:-0.03-0.08), though 95% CIs included the null. We did not observe strong evidence of associations between PFAS and GWG in this cohort. Our findings are consistent with one prior study suggesting that PFOA and PFOS are associated with modest increases in GWG. Additional investigation of the association of PFAS with GWG in larger cohorts would be informative to the field.

#### **004.01.46. Exposure to Perfluoroalkyl Substances and Longitudinal Alterations in Glucose Metabolism among Overweight and Obese Hispanic Children: A Metabolomics Approach**

Tanya Alderete

*Tanya L. Alderete<sup>2</sup>, Ran Jin<sup>1</sup>, Douglas I. Walker<sup>4</sup>, Dania Valvi<sup>3</sup>, Kiros Berhane<sup>1</sup>, Frank Gilliland<sup>1</sup>, Michael Goran<sup>1</sup>, Leda Chatzi<sup>1</sup>*

**Abstract:** Background: Animal studies have shown that early life exposure to perfluoroalkyl substances (PFASs) may disturb glucose metabolism. Human evidence is inconsistent and no previous study has examined the prospective associations between exposure to PFASs and repeated measures of glucose metabolism among Hispanic children. Methods: Overweight and obese Hispanic children (8-14 years) from urban Los Angeles (n=40) underwent clinical measures and 2-hour oral glucose tolerance tests (OGTT) at baseline and follow-up visits (range: 1-3 years). PFASs [perfluorooctanoic acid (PFOA), perfluorooctane sulfonate (PFOS) and perfluorohexane sulfonic acid (PFHxS)] and untargeted metabolic profiling (~4000 metabolites) of baseline serum samples were measured by high resolution mass spectrometry. Linear regression models were used to assess associations between baseline PFASs and changes in metabolic outcomes over follow-up after adjusting for confounders including age, sex, adiposity and puberty status. Network correlation and cluster analyses identified metabolic responses to PFASs that were characterized by pathway enrichment analysis using Mummichog. Results: Each ln-unit increase in PFOA and PFHxS concentrations was associated with a 26.3 mg/dL (95% CI: 4.9-47.7) and 9.6 mg/dL (95% CI: 1.7-17.6) increase in 2-hour glucose levels, respectively. A ln-unit increase in PFHxS concentrations was also associated with a 18.2 mg/dL increase in the glucose area under the curve (95% CI: 2.6-33.8). Metabolome-wide associations identified 615, 974 and 132 metabolic features associated with PFOA, PFOS and PFHxS, respectively after correcting for multiple comparisons. Pathway analysis showed significant alterations of methionine and cysteine metabolism, hexose phosphorylation, and glycerophospholipid and glycosphingolipid metabolism that were associated with PFASs exposure. Conclusions: This first pilot analysis provides evidence that PFASs exposure may exert diabetogenic effects in Hispanic youth.

Abstract: Per- and polyfluoroalkyl substances (PFASs) may interfere with lipid regulation but most previous studies examined occupational cohorts or general populations but not those with high metabolic risks. Among 957 adults in the Diabetes Prevention Program, we measured plasma concentrations of 6 PFASs and lipoproteins at recruitment (1996-1999) and examined their cross-sectional associations using linear regression adjusting for potential confounding by demographic and lifestyle variables. We excluded 69 participants taking lipid lowering medications or had missing values. Plasma PFAS for the 888 participants were comparable to those reported in NHANES 1999-2000. 59.3% of participants had total cholesterol above 200mg/dL. Median levels of several lipid were higher in the 4th compared to the 1st quartile of summed PFASs. Specifically, median total cholesterol was 4.2% (95% CI: 0.9-7.6%) or 8.5mg/dL higher in the 4th comparing to the 1st quartile; 14.6% (95% CI: 4.7-24.5%) for triglycerides (21.2 mg/dL); 5.9% (95% CI: 1.4-10.3%) for non-HDL (5.9 mg/dL); 6.1% (95% CI: 1.1-11.1%) for HDL/Total Cholesterol ratio (0.3) ; and 14.9% (95% CI: 5.2-24.7%) for vLDL (4.3 mg/dL). We also observed positive associations of perfluorooctanesulfonic acid (PFOS), perfluorooctanoic acid (PFOA), perfluorohexane sulfonic acid (PFHxS), and perfluorononanoic acid (PFNA) with total cholesterol, non-HDL, and very low-density LDL (vLDL). We found negative associations for PFOA with LDL particle size and N-ethyl-perfluorooctane sulfonamide acetic acid (EtFOSAA) with HDL. In this pre-diabetic population, higher plasma PFAS levels were cross-sectionally associated with higher blood lipids. Positive associations of PFOS and PFOA with total cholesterol were consistent with previous studies. This study added new findings for EtFOSAA, N-Methyl-perfluorooctane sulfonamide acetic acid, non-HDL, vLDL, and LDL particle size which are clinically relevant lipid parameters.

#### **004.01.48. Perfluoroalkyl Substances and Growth Outcomes through Puberty: Windows of Exposure Susceptibility**

*4. Department of Occupational Medicine and Public Health, The Faroese Hospital System, Tórshavn, Faroe Islands.*

**Abstract:** Background: Emerging evidence show growth deviations associated with developmental exposure to perfluoroalkyl substances (PFASs), but the existence of exposure windows with increased susceptibility needs clarification. Aim: We evaluated the associations of perinatal, mid-childhood and puberty PFAS exposures with serum concentrations of insulin-like growth factor 1 (IGF1) and body mass index (BMI) through puberty. Methods: We examined 1393 children from two Faroese cohorts born in 1986-1987 (N=851) and 1998-2000 (N=542). PFASs were measured perinatally (cord blood or maternal serum), and in child's serum at ages 7 and 14 years. We calculated z-scores for serum-IGF1 and its binding protein (IGFBP3) at age 7 using sex- and cohort-specific means, and for BMI at ages 7 and 14, using sex- and age- specific means of the CDC Growth Charts. To evaluate differences in the associations between exposure windows, we used multivariable-adjusted generalized estimating equations fitting an interaction term between PFAS and developmental stage. Results: Associations were fairly homogeneous between cohorts (P-cohort int.>0.10 for most comparisons), despite differences in exposure ranges. Boys showed patterns of negative associations that were significant only for mid-childhood PFOS and concomitant IGF1 concentrations ( $\beta$ [95% CI] per PFOS doubling=-0.26 [-0.49,-0.04]), and for PFHxS exposure across all periods and BMI at age 14 ( $\beta$ [95% CI]=-0.09 [-0.17,-0.01]). In contrast, girls mostly showed positive associations that were significant for PFOS exposure across all periods and BMI through age 14 ( $\beta$ [95% CI]=0.08 [0.01,0.16]) and between mid-childhood PFOS, PFHxS and PFDA and IGF1 concentrations (e.g., PFOS:  $\beta$ [95% CI]=0.32 [0.06,0.58]). No clear association patterns were seen for PFOA and PFNA. Conclusion: This study suggests that not only prenatal but also postnatal PFAS exposures are associated with growth through puberty, and associations differ according to the developmental stage and sex.

**Abstract:** The prenatal period is a critical time for neurodevelopment and is thus a period of vulnerability during which a range of neurotoxic exposures have been found to exert persistent changes in brain development and behavior. Polybrominated diphenyl ethers (PBDEs), historically used as flame retardants in commercial products, are well-known developmental neurotoxicants. PBDEs were phased out of production a decade ago, but remains measurable in human populations due to their lipophilic properties and continued release from existing consumer products. Despite strong animal and epidemiological evidence of developmental neurotoxicity, the neural substrates linking prenatal PBDE serum concentrations to impaired neurodevelopment are poorly understood. In the present study, we used resting state functional magnetic resonance (fMRI) to examine associations between prenatal PBDEs measured in maternal blood samples and intrinsic functional network organization (i.e., global and local efficiency; measured using a graph-theoretical approach) in 5-year-old children (n = 34). We explored whether PBDE serum concentrations are associated with executive functioning (EF) assessed using a parent-report questionnaire (BRIEF-P) (n = 106) and whether changes in intrinsic functional network organization mediated the association between prenatal PBDE serum concentrations and reported EF problems (n = 34). Children with higher prenatal PBDE serum concentrations showed increased global efficiency of brain areas involved in visual attention (e.g., inferior occipital gyrus) and more reported EF problems. Higher global efficiency of brain areas involved in visual attention was associated with more reported EF problems. Together, these findings suggest that changes in intrinsic functional network organization of visual attention areas may link prenatal PBDE serum concentrations to EF problems in childhood.

## **S04.01.02. Understanding the Associations between Prenatal Dentine Manganese Exposure and Neurodevelopment through the Fusion of Multitask MRI Data**

Abstract: Manganese is a naturally occurring metal that is both an essential nutrient at lower levels and a neurotoxicant at higher levels. Recent studies suggest that higher prenatal manganese exposure results in motor and neurobehavioral deficiencies, demonstrating that the disruption of neurodevelopment during pregnancy by manganese may have long-term consequences for neural function and behavior. However, the neuropsychological tests employed by these studies are unable to quantify the neurophysiological effects that underlie the observed changes. In order to gain a deeper understanding of the impact of prenatal manganese exposure on neural circuitry, we utilize functional magnetic resonance imaging (fMRI) data from two tasks: An N-back (i.e., working memory) task and a finger tapping (i.e., motor) task. The data was gathered from 23 Italian adolescents (aged 15-23 years) and prenatal manganese exposure was assessed using laser ablation inductively coupled plasma mass spectroscopy of deciduous teeth (area under the curve values,  $0.42 \pm 0.19$ ). Since both fMRI tasks are expected to highlight complementary regions associated with prenatal manganese exposure, we exploit a data fusion technique, joint independent component analysis (jICA), to jointly analyze the data, thus enabling greater understanding of the associations between prenatal manganese and subsequent neural function. We find two jICA components suggesting that dentine manganese is positively associated with activation in the somatosensory cortex; a one unit increase in dentine manganese is associated with a 0.35 and 0.26 standard deviation increase in activation of the somatosensory cortex for each component, respectively. These results remain significant after adjusting for multiple comparisons and may suggest inefficiencies in motor control that will be explored using a greater number of subjects and through incorporation of the performance metrics from the tasks themselves.

### **S04.01.03. Prenatal Polybrominated Diphenyl Ether (PBDE) Concentrations and Functional Connectivity of the Reading Network in a Community Sample of 5 Year-Old Children**

Amy Margolis

*Amy Margolis<sup>3</sup>, Sarah Banker<sup>3</sup>, David Pagliaccio<sup>3</sup>, Anny Bonilla<sup>1</sup>, Erik de Water<sup>1</sup>, Julie Herbstman<sup>2</sup>, Robin Whyatt<sup>3</sup>, Ravi Bansal<sup>4</sup>, Bradley Peterson<sup>4</sup>, Pam Factor-Litvak<sup>3</sup>, Megan Horton<sup>1</sup>*

- 2. Environmental Health Sciences, Columbia University, New York City, NY, United States.*
- 3. Columbia University, New York City, NY, United States.*
- 4. CHLA, LA, CA, United States.*

**Abstract:** Objective: Examine associations between PBDE concentrations and functional connectivity of the reading network (RN) in a community sample. Method: Resting State fMRI data (rsfMRI) were acquired from 33 five year-olds in a longitudinal birth cohort. Maternal serum PBDE concentrations ( $\Sigma$ PBDE = sum of log concentrations of 4 most frequently detected congeners 47, 99, 100 and 153) were measured at 12.2 $\pm$ 2.8 weeks gestation (mean $\pm$ SD) using isotope dilution high resolution mass spectrometry. Using the CONN toolbox, we assessed connectivity of the RN, and associations between  $\Sigma$ PBDE and network architecture. The RN was defined by 12 regions of interest identified in task fMRI meta-analyses; the graph network was created with a fixed cost threshold (0.15). We evaluated associations between reading ability (Woodcock Reading Mastery Test Word Identification) and  $\Sigma$ PBDE, and graph theoretical output from the RN, controlling for age, sex, verbal IQ, birthweight, and mean motion. Associations between  $\Sigma$ PBDE and Default Mode Network (DMN) architecture assessed specificity of findings. Results: RN regions were significantly intercorrelated ( $t(31)= 5653.7$   $p<.0001$ ), as expected. As prenatal  $\Sigma$ PBDE increased, global efficiency of the RN decreased ( $b=-0.02$ ,  $T=-2.64$ ,  $p=.014$ ). Greater RN global efficiency was associated with better word reading ( $r= 0.399$ ,  $p=0.059$ ).  $\Sigma$ PBDE did not associate with global efficiency of the DMN ( $b -0.00$ ,  $T = -0.43$ ,  $p =.67$ ) or word reading ( $b 0.92$ ,  $T = 0.16$ ,  $p =.87$ ). Conclusion: This is the first rsfMRI study to assess integrity of the RN and associations between prenatal PBDE concentrations and network architecture. Despite being emerging readers, 5-year-old children showed integrity of the functional RN. Increased global efficiency of the RN was associated with better word reading. Additionally, prenatal PBDE concentrations were inversely associated with global efficiency of the RN but not the DMN, suggesting that PBDE may differentially affect RN network integrity.

#### **S04.01.04. Growing Up in Cincinnati: The Neuroimaging Effects of Ubiquitous Environmental Exposures**

Kim Cecil

*Kim Cecil<sup>1</sup>*

*1. Radiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States.*

**Abstract:** Introduction and Background Researchers in Cincinnati have a long history of studying environmental cohorts. The Cincinnati Lead Study (CLS), a birth cohort initiated in 1979, recruited pregnant women from regions of the city known to have lead hazards with homes constructed prior to the 1940's and positioned near major highways. The Cincinnati Childhood Allergy and Air Pollution Study (CCAAPS) recruited from 2001-2003 using birth records to enroll families with newborns living either within 400 meters of major highways or further than 1 kilometers. From 2003-2006, the Health Outcomes and Measures of the Environment (HOME) study enrolled pregnant women and their offspring to examine common toxicants, including metals, flame retardants, perfluorinated substances and other potential neurotoxicants. We employed multimodal magnetic resonance imaging (MRI) and spectroscopy (MRS) in these cohorts to evaluate the association of selected environmental exposures and neuroimaging outcomes. Methods Participant exposures were characterized throughout childhood. MRI/S evaluations were obtained for the CCAAPS and HOME cohorts at approximately 12 years of age and at several timepoints starting about 21 years of age in the CLS cohort. Results For the CLS, higher mean childhood blood lead concentrations were associated with significant decrements in gray and white matter volumes for several regions, such as the frontal and parietal lobes. Reduced functional activation in Broca's and Wernicke's areas while performing a verb generation task corresponded with higher childhood blood concentrations. However, increased functional activation within the contralateral hemisphere was noted. Conclusions Our data find that environmental exposures influence brain development with structural, organizational and functional alterations revealed by several types of neuroimaging assessments in children and adults.

## **S04.01.05. Early Life Environmental Exposures and Brain Structural Alterations in Childhood**

**Abstract:** Background. Several environmental exposures have been related to impaired child neurodevelopment. However, they mainly used neuropsychological or clinical instruments to evaluate child neurodevelopment, limiting our understanding of which brain structural and functional alterations underlie these associations. We aimed to assess the relationship between several environmental exposures and brain morphology, cortical thickness, and white matter microstructure in children aged 6 to 12 years old. Methods. We used data from the Generation R study, a population-based birth cohort study set up in Rotterdam, The Netherlands (n=9,779, 2002-2006). Several environmental exposures have been estimated during fetal life and childhood including traffic-related air pollution, noise, and organophosphate pesticides. Selected children were scanned at 6-10 years (n=1,070) and the whole cohort was invited to be scanned at the 8-12 years (n=3,992). Structural imaging assessed cortical thickness and volumetric parameters. Diffusion tensor images assessed white matter microstructure. Results. Higher fetal particulate matter levels were related to thinner cortex in several brain regions at 6-10 years old (e.g. cerebral cortex in the precuneus region was 0.045mm thinner (95%CI 0.028-0.062) for each 5µg/m<sup>3</sup> increase in PM<sub>2.5</sub>). The reduced cerebral cortex in some brain regions partially mediated the association between PM<sub>2.5</sub> and impaired inhibitory control. Higher fetal exposure to PM<sub>2.5</sub> absorbance and childhood exposure to NO<sub>x</sub>, oxidative potential of PM<sub>2.5</sub>, and zinc content of PM<sub>2.5</sub> were associated with white matter alterations at 8-12 years old. No relationship was found between fetal noise exposure and white matter microstructure. Conclusions. The use of MRI is gaining ground, making it possible to identify the structural and functional brain alterations that underlie the associations between environmental exposures and children's neurodevelopment in a non-invasive way.

S04.01B. The Impact of Long-Range Wildfire Smoke Plumes on Air Quality and Health  
**S04.01.07. Fine Particulate Matter from Wildfires and Risk of Hospital Admissions in the Western United States**

Michelle Bell

*Jia C. Liu<sup>2</sup>, Michelle Bell<sup>1</sup>*

*1. Yale University, New Haven, CT, United States.*

*2. Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States.*

Abstract: Wildfire can dramatically increase the levels of fine particulate matter (PM<sub>2.5</sub>) in affected areas, resulting in potential health risks. As air monitors cannot separate the PM<sub>2.5</sub> specifically from wildfires from those from other sources and have limited spatial and temporal resolution, new methods are needed to assess the health impact of wildfire-specific PM<sub>2.5</sub>. Further, this pollutant has a unique "high-and-rare" frequency distribution. We estimated the wildfire-specific PM<sub>2.5</sub> at the county level in the Western US during 2004-2009 using the GEOS-Chem model based on Global Fire Emissions Database, and created a new concept called a "smoke wave" (days of high PM<sub>2.5</sub> from wildfire smoke) to systematically quantify the frequency, length, and intensity of wildfire smoke events for 369 US counties. We found that an average Western US county experienced 4-5 smoke wave days/year, and the average smoke wave intensity was 33 micrograms/m<sup>3</sup>. Linking county-level wildfire-specific PM<sub>2.5</sub> to county-level Medicare hospital admission data, we found that intense wildfire smoke episodes are associated with a 7.2% (95%: 0.25%, 15%) increase in respiratory admission rates among Medicare populations in the Western US. The results implied potentially severe health impact of wildfire smoke, a growing threat in the Western US under the impact of hotter and drier summers due to climate change.

#### **S04.01.08. Health Impacts Associated with Fine Particulate Matter and Ozone during a Wildfire: Evidence of Differential Effects Due to Measures of the Social Environment**

Abstract: Wildfires have been increasing in frequency in the western US with the 2017 fire season experiencing some of the worst wildfires in terms of suppression costs and air pollution that the western US has seen. Although there is growing evidence of respiratory exacerbations from elevated fine particulate matter (PM<sub>2.5</sub>) during wildfires, significantly less is known about the impacts of ozone from wildfires on human health. Using machine learning, we created daily surface concentrations maps for PM<sub>2.5</sub> and ozone during an intense wildfire in California in 2008. We then linked these daily exposures to counts of hospitalizations and emergency department visits at the ZIP code level during the wildfire period. We calculated relative risks of respiratory and cardiovascular health outcomes using Poisson generalized estimating equations models for each pollutant in separate and mutually-adjusted models, additionally adjusted for pertinent covariates. We additionally investigated effect modification by various measures of socio-economic status, and racial diversity by ZIP code. We found that PM<sub>2.5</sub> was significantly associated with exacerbations of asthma and chronic obstructive pulmonary disease (COPD) and that these effects remained after controlling for ozone. Effect estimates of ozone during the fires were non-significant. In general, we found that asthma was significantly associated with PM<sub>2.5</sub> during wildfires in ZIP codes in all levels of various socio-economic variables, however, we found significant relationships for COPD for more economically disadvantaged ZIP codes, and for ZIP codes with lower levels of concentrated immigration and with moderate (as compared to lower and higher) levels of racial diversity. Understanding differential risk of health impacts from wildfire smoke is increasingly important as wildfires are contributing more to our air pollution exposures, particularly in western North America.

### **S04.01.09. Impact of Long-Range Wildfire Smoke Plumes on Air Quality in New York City over the Past 10 Years**

Abstract: Hundreds of wildfires burn through the western US and Canada every year in recent decades. Climate change is increasing the prevalence and severity of wildfires, resulting in longer fire seasons and larger area burned. Large wildfires can inject smoke kilometres into the troposphere, where it can be transported in plumes for long distances, even on continental scales. Depending on their height and atmospheric dynamics, plumes can either pass over cities above the boundary layer with little to no effect on local air quality or subside into the planetary-boundary-layer (PBL) and mix with surface air, impacting local air quality. Evidence has shown that the adverse health effects (e.g., a significant increase in mortality and hospitalization rates for respiratory outcomes) were associated with smoke exposure in impacted areas both close to and far away from the fires. In this study, local LiDAR data, EPA AirNow hourly polluted data, and IMPROVE daily data were combined to investigate the impact of wildfire smoke plume on local air quality in NYC. Thirty events (from 2007 to 2016) were first determined by HMS smoke and fire product and local LiDAR profile. Based on plume height, HYSPLIT back-trajectory was used to track whether the plumes were originated from the wildfire regions. Through this study we found that 1) LiDAR can unambiguously identify the mixing of plume with local air in NYC; 2) Wildfire smoke plumes impacts NYC about 3 to 6 times a year, totaling a duration of 20 to 30 days. Plume contributes about 10 to 20% of total PM<sub>2.5</sub> in NYC; 3) During these events, PM<sub>2.5</sub> can reach to 40 to 60 µg/m<sup>3</sup> for several days, above the 35 µg/m<sup>3</sup> NAAQS standard; 4) Plumes contain elevated levels of PM, EC, iron, soil components, ammonium sulphate, etc., some of which can lead to adverse health effects.

#### **S04.01.10. Satellite-Based Daily PM<sub>2.5</sub> Estimates during Fire Seasons in Colorado**

*3. Department of Civil & Environmental Engineering, University of Tennessee, Knoxville, TN, United States.*

**Abstract:** The Western United States has experienced increasing wildfire activities, which have negative effects on human health. Epidemiological studies on wildfire PM<sub>2.5</sub> are limited by the lack of high-resolution PM<sub>2.5</sub> exposure data over fire days. Satellite-based aerosol optical depth (AOD) data provides additional information in ground PM<sub>2.5</sub> concentrations and has been widely used in previous studies. However, the low background concentration, complex terrain and large wildfire sources add to the challenge of estimating wildfire PM<sub>2.5</sub> concentrations. In this study, we applied a Bayesian ensemble model that combined information from the 1 km resolution AOD products, CMAQ model simulations and ground measurements to predict daily PM<sub>2.5</sub> concentrations over fire seasons in Colorado for 2011–2014. Our model had an out-of-sample R<sup>2</sup> of 0.66 and cross-validated root-mean-squared error of 2.00 µg/m<sup>3</sup>. Elevated PM<sub>2.5</sub> concentrations over large fire events were successfully captured. The modeling technique demonstrated in this study could support future short-term and long-term epidemiological studies of wildfire PM<sub>2.5</sub>.

#### **S04.01.11. Forecasting Air Pollution in Australia from the Long-Range Transport of Wildfire Smoke and Prescribed Burns**

Martin Cope

*Martin Cope*<sup>1</sup>

*1. Climate Science Centre, CSIRO, Aspendale, VIC, Australia.*

Abstract: Wildfires are a frequent occurrence in Australia, caused by lightning strikes, power line failures or human interventions. Prescribed burning is one of the principal tools used to mitigate the frequency and intensity of wildfires. Prescribed burning is also extensively used for landscape management- particularly in the Northern Territory of Australia. However, the smoke from wildfires and prescribed burning also has the potential to significantly impact regional and urban air quality and population health, and thus it is important to include this consideration when managing ambient fires. Smoke transport is not constrained by state boundaries and there are many examples in Australia where regional transport has led to over-the-horizon impacts of smoke from remote sources. This is challenging for state-based land management agencies who are tasked with undertaking prescribed burns within the constraint that the combined (all sources) air pollution downwind of a burn has a minimal impact on an exposed population. The Australian Bureau of Meteorology has recently commenced daily forecasts of air pollution (with an emphasis on smoke) using AQFx, a multi-tiered system which includes a numerical air quality forecasting model. AQFx generates 24-72 hour forecasts over a domain which spans Australia and focuses on Victoria and Tasmania, two of the eastern states, with a population of over 4 million people. In this presentation we will explore case studies where AQFx forecasts and observations indicate that significant regional transport of smoke from wildfires or prescribed burns has occurred. We will highlight cases of population responses to the smoke exposure and consider how the use of regional air quality forecasting may be used to mitigate the impact of over-the-horizon smoke transport events on affected populations.

#### **S04.01.12. Characterizing the Level and Distribution of Wildland Fire Smoke Impacts in the U.S. among Susceptible Populations**

Neal Fann

*1. Health and Environmental Impacts Division, U.S. Environmental Protection Agency, Durham, NC, United States.*

*2. NHEERL, Office of Research and Development, Chapel Hill, NC, United States.*

Abstract: Wildland fires are a significant source of fine particles (PM<sub>2.5</sub>) in the atmosphere. Previous research has explored the air quality and human health impacts of wildland fire events over a multi-year period in the United States. Less well understood is how wildland fires affect populations most susceptible and vulnerable to poor air quality. In this analysis, we characterize the wildland fire-attributable exposure and PM<sub>2.5</sub> related mortality and morbidity impacts among several subpopulations between 2008 and 2012. Following approaches previously employed in the literature, we operationalize the terms susceptible and vulnerable according to a variety of attributes that can be observed at the population-level; these include age, race, ethnicity and baseline rate of mortality and morbidity. We also draw from approaches used within the Environmental Justice literature-the Gini Coefficient and Atkinson Index in particular-to quantify the level of mortality and morbidity risk inequality within susceptible and vulnerable groups and between these groups and the rest of the population affected by wildland smoke. We explore the extent to which the extent and intensity of wildland fire events are associated with greater or lesser risk inequality among these subgroups over this five-year period.

## O04.02A. Building Ventilation and Indoor Air Quality: Monitoring, Intervention, Risk Assessment, and Benefits Analysis

### O04.02.01. Continuous Monitoring of PM2.5 in Finnish Office Buildings

Samy Clinchard

*Salvatore della Vecchia<sup>1</sup>, Samy Clinchard<sup>1</sup>, Tomas Novotny<sup>1</sup>, Rick Aller<sup>1</sup>, Ulla Haverinen-Shaughnessy<sup>1</sup>*

*1. 720 Degrees, Helsinki, Finland.*

Abstract: Indoor air quality (IAQ) parameters including temperature, relative humidity, carbon dioxide (CO<sub>2</sub>), volatile organic compounds (VOCs), and particulate matter (PM) concentrations are monitored continuously (15 s interval) in the breathing zone of Finnish office buildings (average five rooms per building). A general goal is to develop IAQ monitoring and analytics supporting building owners' decisions from the point of view of occupants' health and productivity. This study focuses on PM<sub>2.5</sub> monitoring during 10/2016-3/2018 in 73 buildings: 1) 53 from Helsinki metropolitan area and 2) 20 from other areas. The monitoring was conducted with PM probes using laser diffraction technology (light scattering) with 1µg/m<sup>3</sup> resolution and 0-950 µg/m<sup>3</sup> range. In addition, hourly outdoor PM<sub>2.5</sub> data provided by Finnish Meteorological Institute or Breezometer are used in the analyses. Both 24h and 8h (occupied period) averages for indoor PM<sub>2.5</sub> concentrations were < 1 µg/m<sup>3</sup>, whereas outdoor concentrations were about 6 µg/m<sup>3</sup>. All buildings use mechanical ventilation, typically involving filtration of supply air. Without knowing the filter types, the theoretical average reduction from the outdoor levels is about 89% in the metropolitan area, which could be obtained with filters with MERV rating of 12-14. In the other (than metropolitan) areas, indoor concentrations were consistently lower throughout the monitoring period: An average reduction of 96% could be obtained with MERV 14-16. Other possible explanations for low indoor concentrations include high ventilation and air tightness of the building envelope. In reality, there are always some unfiltered air entering indoors, and also indoor sources exist. Recognizing the limitations related to indoor PM detection methodology, we will report temporal variations in indoor PM<sub>2.5</sub> concentrations, as well as the effects of ventilation and building characteristics on the particle infiltration in this relatively large sample of office buildings.

## **O04.02.02. Environmental Interventions in Primary Schools and Its Impacts on Indoor Air Quality and Student Health**

Nan Yan

*1. Environmental Health Sciences, School of Public Health, University of Michigan, Ann Arbor, MI, United States.*

*2. Department of Educational Psychology, Wayne State University, Detroit, MI, United States.*

**Abstract:** Background: Deficient indoor environmental quality (IEQ) in schools could adversely affect the performance and physical health of students and teachers. Ventilation rate and particle filtration are two key factors that influence IEQ. Aims: We present the design and selected results of an intervention study conducted in two schools with 2nd to 4th grade students. We describe a number of innovative outcome measures for both academic performance and physical fitness. Methods: We conducted a blinded case-crossover trial of two interventions, increased ventilation rates and advanced particle filtration, in two primary schools. The school year was divided into five periods; a baseline period and four intervention periods, during which one-half of the classrooms was the treatment group; the other half was not. In each period, we measured IEQ parameters, e.g., optical particle counts (OPC), particulate matter (PM) concentrations, air change rates, volatile organic compounds (VOCs), in four classrooms in each school. Outcome measures, obtained on 629 students, included absenteeism, curriculum-based tests in several academic areas, and the progressive aerobic capacity endurance run (PACER) tests, which measures the cardio-respiratory endurance/aerobic capacity. Results: Interventions altered PM concentrations but did not appear substantially change estimated ventilation rates. We found that the PACER fitness scores varied little between treatment and control groups across intervention periods, but longitudinal analyses showed several changes. The interventions did not appear to alter absenteeism. Results for the two schools differed, possibly reflecting the ability to successfully implement interventions. Conclusions: The study suggests the potential of intervention studies in schools for identifying strategies that benefit indoor air quality and students' physical health, and suggests the need to control for time varying factors that may influence outcomes.

### **004.02.03. Quantifying the Impact of Energy-Efficient Housing Interventions on Indoor Air Quality and Energy Consumption Using Energy, Airflow, and IAQ Co-Simulation**

Lindsay Underhill

*2. Engineering Laboratory, National Institute of Standards and Technology, Gaithersburg, MD, United States.*

**Abstract:** **BACKGROUND.** Residential weatherization retrofits can provide important economic benefits to low-income residents, but can also impact indoor air quality (IAQ). Mechanical ventilation can mitigate IAQ impacts, but can lead to higher energy costs. Furthermore, the combined impact of these measures across diverse multifamily environments has not been well-established. Simulation models provide an efficient means of evaluation, but to date modeling studies have focused on either IAQ or energy without comprehensively evaluating IAQ-energy tradeoffs. **METHODS.** We use a novel co-simulation model of CONTAM and EnergyPlus to simulate the impacts of minimum and high-performance weatherization and ventilation standards on indoor PM<sub>2.5</sub>, gas consumption, and electricity utilization in typical midrise multifamily buildings in the U.S. Unlike previous energy- or IAQ-only models, our co-simulation model can account for the interdependencies between heat transfer, airflows, and contaminant transport in multifamily buildings. We simulated 648 factorial combinations of weatherization (insulation and sealing), ventilation (exhaust and supply ventilation, local cooking exhaust, and HVAC filtration), and indoor PM<sub>2.5</sub> sources (cooking, smoking, infiltration) to identify IAQ-energy "win-win" scenarios as well as scenarios with IAQ-energy tradeoffs. **DISCUSSION.** We found that IAQ and energy impacts varied by retrofit performance level, mechanical ventilation, indoor sources, and weather. Combined weatherization and ventilation measures meeting minimum standards generally led to energy savings (ranging from 15% to 45%) and reductions in total indoor PM<sub>2.5</sub> (ranging from -1 µg/m<sup>3</sup> to -29 µg/m<sup>3</sup>). Meanwhile, some retrofit combinations exceeding minimum standards led to IAQ disbenefits for heavy cooking or smoking homes or an increase in energy costs due to added supply ventilation. Results demonstrate the utility of our model in identifying interventions that provide both energy and IAQ benefits.

#### **O04.02.04. Energy Savings, Emission Reductions, and Health Co-Benefits of the Green Building Movement**

Piers MacNaughton

*Piers MacNaughton<sup>1</sup>, Xiaodong Cao<sup>1</sup>, Jonathan Buonocore<sup>1</sup>, Memo Cedeno<sup>1</sup>, John Spengler<sup>1</sup>, Aaron Bernstein<sup>1</sup>, Joseph G. Allen<sup>1</sup>*

*1. Environmental Health, Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

**Abstract:** Buildings consume nearly 40% of primary energy production globally. Certified green buildings substantially reduce energy consumption on a per square foot basis; however, the co-benefits to health through reductions in energy use and concomitant reductions in air pollution from fossil fuel power plants have not been examined. We calculated year by year LEED (Leadership in Energy and Environmental Design) certification rates in six countries (United States, China, India, Brazil, Germany and Turkey) and then used data from the Green Building Information Gateway (GBIG) to estimate energy savings in each country each year. Of the green building rating schemes, LEED accounts for 32% of green certified floor space and publically reports energy efficiency data. We employed Harvard's Co-BE Calculator to determine pollutant emissions reductions by country accounting for transient energy mixes and baseline energy use intensities. Co-BE applies the social cost of carbon and the social cost of atmospheric release to translate these reductions into health benefits. Based on modeled energy use, LEED-certified buildings saved \$7.5B in energy costs and averted 33MT of CO<sub>2</sub>, 51kt of SO<sub>2</sub>, 38kt of NO<sub>x</sub> and 10kt of PM<sub>2.5</sub> from entering the atmosphere, which amounts to \$5.8B (lower limit = \$2.3B, upper limit = \$9.1B) in climate and health co-benefits from 2000 to 2016 in the six countries investigated. The U.S. health benefits derive from avoiding an estimated 172-405 premature deaths, 171 hospital admissions, 11,000 asthma exacerbations, 54,000 respiratory symptoms, 21,000 lost days of work, and 16,000 lost days of school. Because the climate and health benefits are nearly equivalent to the energy savings for green buildings in the U.S., and up to ten times higher in developing countries, they provide an important and previously unquantified societal value.

#### **O04.02.05. Variability in Ambient Air Pollution Infiltration and Its Impact on Personal Exposure**

Wenwei Che

*Wenwei Che<sup>1</sup>, Md Shakhaoat Hossain<sup>1</sup>, Alexis K.H. Lau<sup>1</sup>*

*1. The Hong Kong University of Science and Technology, Hong Kong, Not Applicable, Hong Kong.*

Abstract: More than 80% of people living in urban areas that monitor air pollution are exposed to air quality levels that exceed the World Health Organization (WHO) limits. Air pollution is identified as the biggest environmental risk to health by the WHO. To better response to the adverse health effect from air pollution, it's important to understand people's contact with air pollutants in their daily life. Over the past three years, we have carried out a range of exposure measurements in Hong Kong. Concentrations of fine particulate matter (PM<sub>2.5</sub>) and gases (CO, CO<sub>2</sub>, O<sub>3</sub>, NO, NO<sub>2</sub>) were measured using portable air quality monitors in several microenvironments including schools, offices, homes, shopping malls and popular transportation modes, such as the Mass Transit Railway (MTR) subway system, transit buses, trams and minibuses. The results demonstrate substantial variations in exposure concentration among microenvironments, affected by the differences in ventilation systems and ventilation practices, diversity in local emissions, and heterogeneity in outdoor concentrations caused by complex urban morphology, such as street canyons and high-rise buildings. High correlations were found between outdoor and indoor air pollution for microenvironments with natural ventilation, or mechanical ventilation with simple filters. Exposure to PM<sub>2.5</sub> was found to be 2-5 times higher at places with Aluminum filter than those with a HEPA filter. PM and gas concentration measured at some of the transportation modes were highly correlated with outdoor concentrations which may be associated with the proximity of their air intakes to the roadside air pollution. Preliminary 24-h personal exposure measurements suggest that microenvironments with high infiltration from outdoor air pollution contribute substantially to the total exposure throughout the day. The collected data and results will aid in developing estimates of human exposure and designing air pollution exposure management strategies.

#### **O04.02.06. Tightening Standards for Indoor Levels of PM2.5: A Promising Approach for Reducing PM2.5 Associated Mortalities in Urban China**

Yinping Zhang

*Jianbang Xiang<sup>1</sup>, Charles J. Weschler<sup>2</sup>, Qingqin Wang<sup>3</sup>, Lin Zhang<sup>1</sup>, Jinhan Mo<sup>1</sup>, Rui Ma<sup>1</sup>, Junfeng (Jim) Zhang<sup>4</sup>, Yinping Zhang<sup>1</sup>*

- 1. Tsinghua University, Beijing, Beijing, China.*
- 2. Rutgers University, Piscataway, NJ, United States.*
- 3. China Academy of Building Research, Beijing, China.*
- 4. Duke University, Durham, NC, United States.*

**Abstract:** Outdoor PM<sub>2.5</sub> pollution in China has been estimated to cause more than one million premature mortalities annually. In urban areas residents spend a major fraction of their time indoors, meaning that a large fraction of urban exposure to "outdoor PM<sub>2.5</sub>" occurs indoors. This study estimates premature adult mortalities attributed to PM<sub>2.5</sub> across urban China in 2015 and the corresponding mortality reductions achieved by meeting the yearly-averaged indoor PM<sub>2.5</sub> threshold in the newly established Assessment Standard for Healthy Building (ASHB) and seven other potential thresholds. We use outdoor PM<sub>2.5</sub> concentrations from 1497 monitoring sites in 366 cities in China, coupled with a detailed exposure model, to estimate outdoor and indoor exposures to PM<sub>2.5</sub> originating outdoors. We proceed to calculate premature mortality attributable to PM<sub>2.5</sub> exposure using an integrated exposure-response model. Results indicate that indoor exposures accounted for 66%-87% of total exposure to PM<sub>2.5</sub> of outdoor origin and 76% (248,174) of the 328,362 premature mortalities attributable to "outdoor PM<sub>2.5</sub>" for the urban population ≥25 years of age in China in 2015. Stroke, ischemic heart disease, chronic obstructive pulmonary disease, and lung cancer mortalities attributable to indoor exposure were 132,209, 71,960, 24,233 and 19,773, respectively. Potentially 10,172 deaths could be avoided if indoor PM<sub>2.5</sub> of outdoor origin met the current ASHB standard of 35 µg/m<sup>3</sup> as annual mean, and 113,219 deaths could be avoided by meeting a 10 µg/m<sup>3</sup> threshold. The findings demonstrate the effectiveness of reducing indoor exposures to "outdoor PM<sub>2.5</sub>" in reducing premature mortalities attributable to urban PM<sub>2.5</sub> pollution in China. Estimates of mortality reductions associated with various indoor PM<sub>2.5</sub> thresholds can help formulate indoor air quality policies and practices, including building- or room-based filtration of ventilation air.

## 004.02B. Effects of Temperature 2

### **004.02.07. Interactive Effects of Air Pollution and Air Temperature on Preterm Delivery in 24 Major Cities across Canada**

Eric Lavigne

*Eric Lavigne<sup>1</sup>, Li Chen<sup>1</sup>, Dave Stieb<sup>1</sup>*

*1. Health Canada, Ottawa, ON, Canada.*

**Abstract:** Background: Epidemiological studies have reported associations between preterm birth and short-term exposure to ambient air pollution and air temperature. However, it remains uncertain whether there are interactive effects of air pollution and temperature on risk of preterm birth. We investigated whether short-term associations of ambient air pollution were modified by air temperature and whether air pollution levels affected the temperature-preterm birth associations in 24 major cities across Canada. Methods: We first analyzed air temperature-stratified associations between air pollution and preterm birth as well as air pollution-stratified temperature-preterm birth associations using city-specific Cox proportional hazards models with a distributed lag nonlinear temperature term in each city. All models were adjusted for individual-level confounders. City-specific effect estimates were then pooled using random-effects meta-analysis. Results: Pooled associations between air pollutants and risk of preterm delivery were overall positive and generally stronger at high relatively compared to low air temperatures. For example, on lag-0 (i.e. same day of preterm delivery) with high air temperatures (>75th percentile), an increase of 7.4  $\mu\text{g}/\text{m}^3$  in PM<sub>2.5</sub> corresponded to a 2.51% (95% CI: 0.39%, 4.67%) increase in preterm delivery, which was significantly higher than that on days with low air temperatures (<25th percentile) [-0.18% (95%CI: -0.97%, 0.62%)]. On days with high air pollution (>50th percentile), both heat- and cold-related preterm delivery risks increased. Conclusion: Our findings showed that the association between preterm delivery and air pollution was modified by air temperature and vice versa. Our findings point to the importance of understanding the combined health effects of ambient air pollution and air temperature.

## **004.02.08. Regional Evidence-Based Extreme Cold Warning Thresholds Using Daily Mortality Data**

Sabit Cakmak

*Sabit Cakmak<sup>1</sup>, Aziz Khanchi<sup>2</sup>, Abderrahmane Yagouti<sup>3</sup>, Chris Hebbern<sup>1</sup>, Melissa MacDonald<sup>3</sup>, Dave Henderson<sup>3</sup>*

- 1. Health Canada, Government of Canada, Ottawa, ON, Canada.*
- 2. Privacy Analytics, Ottawa, ON, Canada.*
- 3. Environment and Climate Change Canada, Gatineau, QC, Canada.*

**Abstract:** Background: During cold-weather spells, weather warnings are issued to the public by local public health units or meteorological departments. Generally, these cold warnings do not rely on epidemiological evidence or on the association between health outcomes and meteorological variables. This study was done in response to a joint request from the Climate Change and Health Office of Health Canada and Environment and Climate Change Canada to develop a data-driven scheme to improve the current cold-health warning system. Objective: This study aimed to use a systematic data-driven approach to improve current cold-health warning systems by modeling the relationship between extreme cold and excess risk of mortality in a regional context. Our specific objective was to relate winter daily maximum temperature to cause-specific mortalities in order to identify extreme cold thresholds that are significantly associated with excess mortality. Methods: Cluster analysis was used to identify meteorological regions. Maximum temperature with lag 0 was chosen as the indicator, and warning thresholds were obtained in order to minimize excess acute myocardial infarction and cerebrovascular disease mortalities. Data recorded between 1981 and 2010 in the province of Manitoba, Canada was used to test the methodology developed in this study. Results: Two main meteorological regions in Manitoba were identified. Regional warning thresholds of winter daily maximum temperatures were obtained. These thresholds were -23 and -28 for the southern and northern regions, respectively. Conclusion: Our study is a first step in providing an information base to develop a data-driven regional cold-weather warning system in Manitoba. The approach presented in this paper is flexible and has the capacity to be applied to other provinces in Canada.

## **O04.02.09. The Role of Humidity in Associations of High Temperature with Mortality: A Multi-City Multi-Country Study**

Ben Armstrong

*Ben Armstrong<sup>1</sup>, Francesco Sera<sup>1</sup>, Antonio Gasparrini<sup>1</sup>*

*1. London School of Hygiene and Tropical Medicine, London, United Kingdom.*

**Abstract:** There is strong experimental evidence that physiologic stress from high temperatures is greater if humidity is higher. However, "heat indices" developed to allow for this have not consistently predicted mortality better than has (dry-bulb) temperature. To clarify, we explored models for daily mortality as a function of both temperature and humidity in a large international dataset. **Methods.** In each of 395 cities in 17 countries we fitted a time series regression model to summer mortality with distributed lag non-linear model (DLNM) for temperature (to lag 3) and supplemented this with a range of terms for relative humidity and its interaction with temperature. City-specific associations were summarised using meta-analytic techniques. **Results.** There was significant variation in the association between cities and countries, with the overall association of humidity with cumulative lag0-3 mortality close to null. At very high temperatures risk did on average rise slightly with high humidity. For example, on average at 99th centile summer temperature (Vs MMT) increase=13.6% at median humidity and 0.8% higher (95%CI 0.1-1.5) at 99th centile humidity. In contrast, below the 90th centile temperature the 99th centile humidity increment was null 0.0%(-0.1,0.2). The humidity-related excess risk was overwhelmingly at lag 0, with high humidity at lag 1 usually associated with LOWER mortality, possibly reflecting an increased risk with upward change in humidity between lags 1 and 0. Results using dewpoint were very similar. **Discussion.** In general, allowing for humidity in addition to temperature added only marginally to ability to predict daily summer mortality in a city in models considering lags 0-2, with risk increments for higher humidity restricted to periods of very high temperature. However, in specific countries or cities atypical for this data set, or for different lag intervals, patterns may be different. On behalf of the MCC Collaborative Research Network.

#### **004.02.10. Increased Impulsivity in Urban-Dwelling Teens: Role of Ambient Air Temperature and Lack of Neighborhood Greenspace**

Diana Younan

*Diana Younan<sup>1</sup>, Lianfa Li<sup>1</sup>, Catherine Tuvblad<sup>3</sup>, Pan Wang<sup>4</sup>, Jun Wu<sup>2</sup>, Meredith Franklin<sup>1</sup>, Frederick Lurmann<sup>5</sup>, Kiros Berhane<sup>1</sup>, Laura Baker<sup>6</sup>, Jiu-Chiuan Chen<sup>1</sup>*

- 1. Preventive Medicine, University of Southern California, Los Angeles, CA, United States.*
- 2. University of California, Irvine, Irvine, CA, United States.*
- 3. Örebro University, Örebro, Sweden.*
- 4. University of California, Los Angeles, Los Angeles, CA, United States.*
- 5. Sonoma Technology, Inc, Petaluma, CA, United States.*
- 6. Psychology, University of Southern California, Los Angeles, CA, United States.*

**Abstract:** Ambient temperature and lack of residential greenspace have been associated with increased externalizing behavior, but the neuropsychological processes are unclear. We conducted a longitudinal analysis to examine the association between temperature, greenspace, and impulsivity in urban-dwelling adolescents. Participants (N=982) of the Risk Factors for Antisocial Behavior Study, a multi-ethnic cohort of Southern California twins/triplets examined in 2000-2014 (aged 9-21 years), each with repeat measures of impulsivity assessed by the Go/No Go test. Ambient temperature near the residence (6.8±3.0 km) were obtained from local Meteorological Information System and Normalized Difference Vegetation Index was used as a proxy for neighborhood greenspace (in 1000-m buffer). A monthly exposure time-series was created and aggregated in short-term (1-, 3-, and 6-month) and long-term (1-, 2-, and 3-year) averages prior to each behavioral assessment. Generalized Poisson mixed models were used to estimate the exposure effects on number of false alarms, adjusting for within-family/-individual correlations and confounders. In separate adjusted analyses, we found average temperature from 1-month to 2-years significantly (all p<0.05) increased impulsivity, while long-term greenspace decreased impulsivity. In models mutually adjusting for temperature and greenspace, the neurotrophic benefits of greenspace disappeared, while the adverse effects of 1- and 3-month temperature remained. These associations could not be explained by sociodemographics, neighborhood quality and socioeconomic characteristics, or season. This is the first epidemiologic evidence supporting the adverse temperature effects on impulsivity, which may contribute to the behavioral effect of diminished greenspace. Future studies need to examine whether increased impulsivity mediates the adverse behavioral effect and how neural networks underlying such neuropsychological processes are perturbed by ambient temperature.

## **O04.02.11. Ambient Temperature and Preterm Birth: A Retrospective Observational Study of 30 Million U.S. Singleton Births**

Shengzhi Sun

*Shengzhi Sun<sup>1</sup>, Kate R. Weinberger<sup>1</sup>, Keith Spangler<sup>1</sup>, Melissa N. Eliot<sup>1</sup>, Gregory A. Wellenius<sup>1</sup>*

*1. Department of Epidemiology, Brown University, Providence, RI, United States.*

**Abstract:** Background: Emerging evidence suggests that prenatal exposure to temperature extremes may be associated with higher risk of preterm birth, but prior studies have been limited by small sample sizes and the results have been heterogeneous. We examined the associations between daily and trimester-mean ambient temperature during pregnancy and preterm birth in the contiguous United States. Methods: We linked 30,326,344 singleton births in 403 US counties between 1989 and 2002 to daily ambient temperature at the county level. Births delivered prior to 37 completed weeks of gestation were considered preterm. We used distributed lag non-linear time-series models to estimate the association of preterm birth with daily temperature in the 2 weeks prior to delivery, and logistic regression to assess the association between preterm birth and average temperatures in the 1st and 2nd trimester. Results: Approximately 2.7 million (9.0%) deliveries were preterm. Extreme heat (99th percentile versus median of county-specific temperatures) in the 2 days prior to delivery was associated with an incidence rate ratio (IRR) of preterm birth of 1.038 (95% CI: 1.027, 1.050) while extreme cold (1st percentile versus median) was associated with an IRR of 0.984 (0.974, 0.994). Warm average temperatures (>90th percentile of county- and trimester-specific temperature distributions versus milder temperatures) during the 1st and 2nd trimester were associated with higher relative risk of preterm birth, with odds ratios of 1.025 (1.019, 1.032) and 1.016 (1.009, 1.023), respectively, while cold average temperatures (<10th percentile) were associated with lower relative risks of preterm birth. Conclusions: Extreme heat - but not cold - during the 3rd trimester may be associated with triggering of preterm birth in the US. Warmer average temperatures in the 1st and 2nd trimesters may also be associated with higher relative risk of preterm birth. Heat may be a novel risk factor for preterm birth in the US.

## **004.02.12. Evaluation of a Smart Phone Application Providing Citizen Services during Extreme Temperature Events: The Treasure and Extrema Projects**

Klea Katsouyanni

"Abstract: Background/Aim: The health effects of extreme temperatures are well documented at population level. Within the TREASURE project, a smartphone application developed to provide services to citizens during heatwaves in Athens is being scaled-up, within the EXTREMA project, to cover several European cities and cold spells. We report here an evaluation of the first application and the plan for further evaluations. Methods: Forty seven volunteers, age range 22-69 years, recruited in July 2016, followed a protocol for using the mobile app during one week. The app returned a heat-related risk in four categories based on personal risk profile and satellite-derived real time temperature at the specific location of the subject. In case of "high risk", instructions for protective measures and guidance for reaching air conditioned municipal sites were provided. The volunteers used the app  $\geq 7$  times/day, recorded the response, temperature and relative humidity indications, and noted the instructions that they followed. They also kept a time-activity diary (TAD) and wore a portable thermometer recording ambient temperature every 5'. Results: A high risk indication was returned 141 times for 18 individuals during 9 different days. Ten subjects reported following instructions for risk reduction. The locations based on the TAD were classified as "home"; "outdoors"; "in transportation"; "indoors" and "at the beach". The highest temperatures were recorded at the beach (32.6°C), followed by "in transportation" (30.5°C). Conclusions: The application was found useful for citizens in Athens during the summer. The problem that often elderly individuals are not using a smart phone may be addressed by supporting multiple profiles in the app by their relatives or using the Municipality public announcement boards. An evaluation with subjects having chronic respiratory diseases and the extension for cold spells is planned. \*TREASURE and EXTREMA projects are co-funded by the European Commission, DG-

## O04.02C. Global Trends in Human Biomonitoring

### **O04.02.13. German Environmental Specimen Bank: Urine Samples from 1999-2017 Document Rapid Increase in Exposure to the Para-Phthalate Plasticizer DEHTP**

Frederik Lessmann

*Frederik Lessmann<sup>1</sup>, Holger M. Koch<sup>2</sup>, Claudia Pölmke<sup>2</sup>, Till Weber<sup>3</sup>, Petra Apel<sup>3</sup>, Volker Harth<sup>1</sup>, Thomas Brüning<sup>2</sup>, Marike Kolossa-Gehring<sup>3</sup>*

*2. Institute for Prevention and Occupational Medicine of the German Social Accident Insurance - Institute of the Ruhr-Universität Bochum (IPA), Bochum, Germany.*

*3. German Environment Agency (UBA), Berlin, Germany.*

**Abstract:** Di(2-ethylhexyl) terephthalate (DEHTP) is increasingly used as an alternative to reprotoxic ortho-phthalate plasticizers, e.g. di(2-ethylhexyl) phthalate (DEHP), in everyday products such as food contact materials, toys and medical devices. In Western Europe, DEHTP consumption rose from 2,000 t in 2002, to 100,000 t in 2014 and a predicted 135,000 t in 2019. To investigate for possible increases of DEHTP exposure in the German population over time, we analyzed 600 24-hour urine samples of the German Environmental Specimen Bank for specific DEHTP metabolites as exposure biomarkers. Samples were collected in the years 1999-2017 (ten sampling years, 30 male and 30 female volunteers each, aged 20-29). The samples were blinded and randomized before analysis. Four urinary DEHTP metabolites (side-chain oxidized monoesters) were determined by online SPE LC-MS/MS with isotope dilution quantification. The limits of quantification were 0.2 µg/L (5cx-MEPTP and 5oxo-MEHTP), 0.3 µg/L (5OH-MEHTP) and 0.4 µg/L (2cx-MMHTP). From 1999 until 2009 the main oxidized DEHTP metabolite 5cx-MEPTP was rarely detected. Afterwards, detection rates increased significantly (8% in 2009, 42% in 2011, 95% in 2013, 98% in 2015, and 100% in 2017). The median concentration for 5cx-MEPTP increased from For the first time, we document the increasing exposure to DEHTP of the German population in a robust set of 600 24-hour urine samples collected between 1999 and 2017. Although considered uncritical for now, the steep increase in DEHTP exposure calls for a continued exposure monitoring.

#### **O04.02.14. Human Exposure to Mercury during the Last Half-Century: Worldwide Trends in Human Blood and Breast Milk Levels and Their Implications on Health**

Brij Sharma

*Brij M. Sharma<sup>1</sup>, Ondrej Sanka<sup>1</sup>, Jiri Kalina<sup>1</sup>, Martin Scheringer<sup>1</sup>*

*1. Research Centre for Toxic Compounds in the Environment, Masaryk University, Brno, Czechia.*

Abstract: Mercury is a pollutant of global concern. It has been found in various biological media including human blood and breast milk, globally. This study assesses global and regional trends of mercury levels in human blood and breast milk in the last half-century. This study also provides an overview of epidemiological literature showing evidence of associations between mercury exposure and various human health conditions. We searched electronic databases to identify articles published prior to June 14, 2017. Our search finalized a pool of 562 studies reporting total mercury levels in whole blood, cord blood, or breast milk and associations with human health conditions. Temporal trends of mercury levels in target media were estimated using a linear fit of the log-transformed data. Choropleth maps were created to provide an overview of worldwide mercury levels in human blood and breast milk. Furthermore, a summary of significant and relevant associations between mercury exposure and human health conditions in children and adults was prepared. We found significant declines in mercury levels in whole blood, cord blood, and breast milk between 1966-2015. A regional overview of mercury exposure suggests highest levels in South America, followed by Africa and Asia. Populations from North America and Europe were found with the lowest mercury exposure levels. We observed conclusive consistent associations of mercury exposure with only selected health conditions, especially neurodevelopment and neurotoxicity in children and adults. For several other health conditions, reported findings do not support conclusive associations. Our study establishes a baseline for the evaluation of mercury levels and health risks that will be measured under the Minamata Convention in the future and highlights the demand for well-designed epidemiological investigations to fully understand the health implications of mercury exposure.

#### **004.02.15. Relationship between AHR Genetics and Dioxin Half-Life in Seveso Women**

Jennifer Ames

*Jennifer Ames<sup>1</sup>, Marcella Warner<sup>1</sup>, Stefano Signorini<sup>2</sup>, Paolo Mocarelli<sup>2</sup>, Paolo Brambilla<sup>2</sup>, Nina T. Holland<sup>1</sup>, Brenda Eskenazi<sup>1</sup>*

*1. Center for Environmental Research & Children's Health (CERCH), University of California, Berkeley, Berkeley, CA, United States.*

*2. Department of Laboratory Medicine, University of Milano-Bicocca, School of Medicine, Hospital of Desio, Desio-Milano, Italy.*

**Abstract:** Background: Biological half-lives of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), an endocrine-disrupting and carcinogenic compound, are long but vary widely in humans (typically 4-10 years) with factors such as dose, age, BMI, and smoking known to play a role. The contribution of genetic variation in the aryl hydrocarbon receptor (AHR), a transcription factor integral to xenobiotic metabolism, remains poorly understood but could have important implications for health. Methods: The Seveso Women's Health Study (SWHS), initiated in 1996, is a cohort of 981 Italian women exposed to TCDD from an industrial explosion in July 1976. We calculated apparent TCDD elimination half-life in a subset of women (n=263) for whom we measured TCDD in blood from two time points: 1) immediately following the accident in 1976 and 2) at study enrollment in 1996. We genotyped 19 single nucleotide polymorphisms (SNPs) across the AHR gene. The relationship between individual SNPs and TCDD half-life was examined with robust multivariate regression, adjusting for other half-life predictors. Results: In our sample, the median (range) of TCDD half-life was 5.2 (1.9-22.0) years. We found two AHR SNPs significantly associated with biological half-life. The variant allele at rs17779352, a synonymous mutation in AHR's basic helix-loop-helix (bHLH) binding domain, was associated with a shorter half-life (adj- $\beta$ =-0.63 years, 95% CI: -1.25, 0.00) while the variant at rs6968865, upstream of AHR in the gene's regulatory region, was associated with a longer half-life (adj- $\beta$ =0.52 years, 95% CI: 0.03, 1.02). Smokers with the variant at rs17779352 had a TCDD half-life that was, on average, 1 year shorter than among non-smokers (pint=0.09). Conclusions: These results suggest that AHR genetics may contribute to TCDD's elimination rate in women, possibly influencing their lifetime sensitivity to TCDD. This is the first study to evaluate the association between genetics and TCDD body burden using longitudinal data.

#### **004.02.16. Persistent Organochlorine Pollutants: Genetic Variations Associated with DDE and PCB153 Blood Levels among Women in France**

Takiy eddine Berrandou

*Takiy Eddine Berrandou<sup>1</sup>, Emilie Cordina-Duverger<sup>1</sup>, Claire Mulot<sup>2</sup>, Thérèse Truong<sup>1</sup>, Pascal Guenet<sup>1</sup>*

*1. Cancer & Environment Group, Center for Research in Epidemiology and Population Health (CESP), INSERM, University Paris-Sud, University Paris-Saclay, Villejuif, France.*

*2. University Paris Descartes, Inserm UMRS 1147 EPIGENETEC, Paris, France.*

**Abstract:** Persistent Organochlorine Pollutants including Dichlorodiphenyltrichloroethane (DDT) and polychlorinated biphenyls (PCBs) are ubiquitous in the environment. Many studies have attempted to link DDT or PCB levels in human tissues to the risk of breast and other cancers. However, little attention has been paid to the genetic determinants of DDT and/or PCBs levels. Our aim was to identify genetic variants modifying blood levels of DDE (the major breakdown product of DDT) and PCB153 measured in a sample of women in France. Blood levels of circulating DDE and PCB153 were measured in 1236 healthy women selected as control subjects in an epidemiological study on breast cancer. We genotyped 474 Single Nucleotide Polymorphisms (SNP) in 54 CYP and GST genes involved in the metabolism of DDT and PCBs. Blood concentrations of DDE and PCB153 were explored in relation to each SNP and to the genetic variation in the genes using the Adaptive Rank Truncated Product method. This approach allows investigating the role of a gene seen as a set of SNPs or of a set of genes in DDE and PCB153 levels, and to gain statistical power as compared to a SNP by SNP approach. P-values were adjusted for multiple testing by False Discovery Rate (FDR) method. Blood levels of DDE and PCB153 were significantly associated with several SNPs located in CYP genes. The top-SNPs were rs8192719 (FDR=3x10<sup>-26</sup>) for DDE and rs7255904 (FDR=0.01) for PCB153, both located in CYP2B6. At the gene level, CYP2B6 was associated with levels of DDE (FDR=2x10<sup>-4</sup>) and PCB153 (FDR=0.01). Genetic variation in the whole gene-set including CYPs and GSTs was significantly associated with blood levels of DDE (p=2x10<sup>-4</sup>) and PCB153 (p=2x10<sup>-4</sup>). These findings show that polymorphisms in genes involved in the metabolism are important determinants of organochlorine compound levels measured in humans, and should be taken into account as possible modifiers of the association between PCB and DDT levels and disease risk in epidemiological studies.

#### **O04.02.17. Biomonitoring-Based Antibiotic Body Burden of Adults in Shanghai**

Hexing Wang

*Hexing Wang<sup>1</sup>, Xin Yu<sup>1</sup>, Qingwu Jiang<sup>1</sup>, Zhijun Zhou<sup>1</sup>*

*1. School of Public Health/ Key Laboratory of Public Health Safety of Ministry of Education, Fudan University, Shanghai, China.*

**Abstract:** Background: Monitoring of common used antibiotics in urines has indicated a heavy antibiotic burden in children and pregnant women in East China, but there is lack of data in adults. Objective: To investigate the antibiotic body burden of adults in Shanghai by analyzing common antibiotics in urines. Methods: A large-scale adult cohort was established to explore the risk factors of chronic diseases in Shanghai between 2016 and 2017. Based on this baseline survey, we randomly selected 530 adults aged 21-75 years from two towns located in the suburb in 2017 and 18 common used antibiotics were determined in their spot urines by the isotope dilution-based UPLC-Q/TOF MS. The antibiotics were from five categories (4 fluoroquinolones, 3 phenicols, 3 tetracyclines, 3 macrolides, and 4 sulfonamides) and there were 4 veterinary antibiotics, 4 human antibiotics, and 10 human/veterinary antibiotics. Results: Except for clarithromycin, other 17 antibiotics were detected in urines and the detection frequencies varied greatly by specific antibiotics with a overall detection frequency of 46.3%. Ciprofloxacin, ofloxacin, trimethoprim, and florfenicol were frequently detected in urine with detection frequencies between 8.1% and 14.9%. The detection frequencies of fluoroquinolones, phenicols, tetracyclines, macrolides, and sulfonamides ranged from 1.9% to 28.7% and for veterinary antibiotics, human antibiotics, and human/veterinary antibiotics, those ranged from 3.2% to 39.1%. The maximum unadjusted concentration of 17 antibiotics ranged from 1.9 ng/ml to 5985.8 ng/ml with four antibiotics beyond 1000 ng/ml. The concentration sum of all antibiotics in antibiotic-positive urines varied between 0.02 ng/ml and 5986.4 ng/ml with a mean of 92.2 ng/ml. Conclusion: Adults were extensively exposed to multiple types of antibiotics in Shanghai and carried a heavy antibiotic body burden. More researches are needed to identify the sources and assess the potential health risks.

## **O04.02.18. Relation of Maternal Serum Concentrations of Persistent Organic Pollutants to Vitamin D in Southern California**

Gayle Windham

*Michelle Pearl<sup>1</sup>, Victor Poon<sup>2</sup>, Darryl Eyles<sup>3</sup>, Kristen Lyall<sup>4</sup>, Martin Kharrazi<sup>1</sup>, Lisa Croen<sup>5</sup>, Gayle Windham<sup>1</sup>*

- 5. Kaiser Division of Research, Oakland, CA, United States.*

**Abstract:** Background/Aim: Low levels of vitamin D in pregnancy are associated with adverse birth and developmental outcomes. Persistent organic pollutants (POPs) are considered endocrine disrupting chemicals and have been suggested to interfere with vitamin D metabolism. Only a few studies of POPs and vitamin D levels have been conducted in humans, but not on polybrominated diphenylethers (PBDEs) or polyfluoroalkyl substances (PFAS). We sought to examine this relation in a population-based sample of pregnant women. Methods: Mother-child pairs with banked biospecimens were sampled as part of a case-control study of children born 2000-2003 in Southern California. 25-Hydroxyvitamin D (OHD), 5 PBDE congeners and 8 PFAS were measured in mid-pregnancy serum from 417 population control mothers. Log-transformed (lipid-adjusted for PBDEs) POPs concentrations were modelled in relation to continuous and categorized OHD (<75nmol/L, or "insufficient", vs. ≥75nmol/L) using linear and logistic regression, adjusting for maternal age, race, education, and parity. Results: Median OHD was 86 nmol/L and 37% of mothers had OHD insufficiency. Increasing 2-(N-ethylperfluorooctane sulfonamido) acetate (Et-PFOSA-AcOH) was inversely associated with OHD, whereas BDE-28 was directly associated with OHD. Higher Et-PFOSA-AcOH was also associated with increased odds of OHD insufficiency (OR=1.3, 95% CI [1.0-1.7]); however higher perfluorononanoate (PFNA), BDE-28, BDE-100 and BDE-153 were associated with decreased odds of OHD insufficiency (OR=0.6, CI [0.4-0.9], OR=0.7, [0.5-0.9], OR= 0.8, [0.6, 0.997] and OR=0.8 [0.6-0.97], respectively). Conclusions: In this first study to examine PFAS and PBDE concentrations in relation to vitamin D levels in pregnancy, associations were found in both directions. These findings highlight the need for additional research to understand these relationships and their potential impact on health outcomes.

## 004.02D. Greenness Effects 3

### 004.02.19. Health Risk Assessment of Community Riverside Regeneration in Barcelona

David Rojas-Rueda

*Cristina Vert Roca<sup>1</sup>, Mark Nieuwenhuijsen<sup>1</sup>, Mireia Gascon<sup>1</sup>, James Greiller<sup>2</sup>, Lora E. Fleming<sup>2</sup>, Mathew White<sup>2</sup>, David Rojas-Rueda<sup>1</sup>*

*1. Barcelona Institute for Global Health (ISGlobal), Barcelona, Spain.*

*2. European Centre for Environment and Health, University of Exeter Medical School, Truro, United Kingdom.*

**Abstract:** Access to natural outdoor environments in cities may promote physical activity and improve human's health and wellbeing. This study aimed to quantify the impacts on the health and health-related economics of an urban riverside regeneration, which consisted on creating the Besòs riverside Park by providing access to the riverbanks and creating a huge green area next to the river. A counting campaign and a survey of riverside Park users describing their physical activity levels, the duration, and frequency of their visits to the regenerated area, were used to estimate their metabolic equivalent of task (MET-min/week). We used a bespoke quantitative risk assessment tool, which related physical activity (in MET-min/week) and health outcomes obtained from existing meta-analyses, to estimate the age and sex-specific health impacts in terms of all-cause mortality, morbidity (including ischemic heart disease; ischemic stroke; type 2 diabetes; cancers of the colon and breast; and dementia) and disability-adjusted life years (DALYs). We conducted a health economic evaluation in terms of the value of statistical life and direct health costs. Almost 6,000 adult users visited the regenerated riverside Park daily and performed different types of physical activities (i.e. walking for leisure or to/from work, cycling, and running). Among these users we estimated an annual reduction of -3.4 (95% CI; -10.8; -0.1) deaths, -6.2 (95% CI; -19.4; -0.5) cases of diseases, and -11 (95% CI; -36.8; -0.5) DALYs. We estimated savings of -11.4 (95% CI; -36.9; -269,642) million Euros on mortality and direct health-care costs. The urban riverside regeneration of the Besòs riverside Park has resulted in substantial quantifiable benefits to the public health in terms of increased physical activity. Similar accessible riverside renewal projects might improve the health of urban populations, mitigating major public health challenges resulting at least partly from physical inactivity.

## **O04.02.20. Associations between Area-Level Greenness and Infant Mortality Rates in Philadelphia, PA**

Leah Schinasi

*Leah H. Schinasi<sup>1</sup>, Harrison Quick<sup>2</sup>*

*1. Environmental and occupational health, Drexel University, Philadelphia, PA, United States.*

*2. Epidemiology and Biostatistics, Drexel University, Philadelphia, PA, United States.*

**Abstract:** In our rapidly urbanizing world, there is great interest in using greening strategies to promote health. A growing body of epidemiologic literature shows that green space protects against mortality among adults. However, few studies have explored the relationship between green space and infant mortality, defined as any death occurring in children under one year of age. We investigated the relationship between overall greenness and census-tract level rates of infant mortality in Philadelphia, PA, for years 2010-2014. Overall greenness in each census tract was estimated using satellite images of the normalized difference vegetation index (NDVI). Census tract level counts of total annual infant mortality cases and births were downloaded from the Vital Statistics Report of the City of Philadelphia. Aggregate numbers of infant deaths and births within each census tract for all years of the study period were calculated. We used Bayesian spatial areal unit, conditional autoregressive models to estimate associations between greenness and infant mortality. The models included a set of random effects to account for spatial autocorrelation between neighboring census tracts. Infant mortality counts were modeled using a Poisson distribution, and the logarithm of total births in each census tract was specified as the offset term. Models were adjusted for census-tract level percentages Black/non-Hispanic and living below the poverty line. Across 371 census tracts, the mortality rate ranged from 0 to 49.5/1,000 births. In adjusted models, the rate of infant mortality was 22% higher in less green compared to more green tracts. In stratified models, the relationship between greenness and infant mortality was stronger in tracts with higher percentages living below the poverty line. These results contribute to mounting evidence that urban greenness is a health promoting environmental asset.

## **O04.02.21. Greater Residential Tree Cover Is Associated with Reduced Stress-Related Physiological Dysregulation in Residents of Central North Carolina**

Andrey Egorov

*Andrey Egorov<sup>1</sup>, Shannon Griffin<sup>1</sup>, Reagan Converse<sup>1</sup>, Jennifer Styles<sup>1</sup>, Elizabeth Sams<sup>1</sup>, Elizabeth Klein<sup>1</sup>, Laura Jackson<sup>1</sup>, Timothy Wade<sup>1</sup>*

*1. U.S. Environmental Protection Agency, Chapel Hill, NC, United States.*

**Abstract:** Background: Urban green spaces have been linked to reduced morbidity and mortality. Alleviation of chronic stress is a hypothesized mechanism of these salutogenic effects. Our previous research showed that greater residential greenness was associated with lower allostatic load suggesting reduced physiologic dysregulation. The objective of this analysis was to assess the effects of different vegetation types on the distribution of allostatic load values. Methods: This cross-sectional study involved 186 adult residents of the Durham-Chapel Hill, NC urban area. High-resolution metrics of tree and grass cover within 500 m of each residence were produced using US EPA EnviroAtlas database. Weighted tree cover measures were produced allowing for an exponential decay of effect with distance from residence. Serum samples were tested for fifteen biomarkers of neuroendocrine, metabolic, and immune functions. Allostatic load was estimated as a standardized distance from the center of a joint multivariate distribution of biomarkers (Mahalanobis distance). Statistical analysis involved two stages: (1) generalized additive regression models of allostatic load on socio-demographic covariates and a thin plate smoothing function of geographic coordinates; and (2) quantile regression of residuals from the 1st stage on a weighted proportion of tree or grass cover. Results: Individuals in the 3rd tertile of tree cover distribution compared to individuals in the 1st tertile had 8% (1%; 15%), 12% (4%; 20%), and 23% (12%; 33%) lower predicted values of the 50th, 75th, and 90th percentiles of the marginal distribution of allostatic load respectively. Grass cover was not a significant predictor of allostatic load. Conclusions: Trees near residence may help to alleviate chronic stress preventing stress-related physiological dysregulation (allostatic load). Health benefits may be stronger in individuals with greater chronic stress. This abstract does not represent EPA policy.

## **O04.02.22. Residential Greenness and Breast Cancer Survival after a Breast Cancer Diagnosis**

Peter James

*Natalie DuPre<sup>1</sup>, Peter James<sup>2</sup>, Jaime E. Hart<sup>1</sup>, Trang VoPham<sup>3</sup>, Cheng Peng<sup>1</sup>, Elizaveta Gazeeva<sup>3</sup>, Veronica M. Vieira<sup>4</sup>, Rulla Tamimi<sup>1</sup>, Francine Laden<sup>3</sup>*

- 1. Brigham and Women's Hospital, Channing Division of Network Medicine, Boston, MA, United States.*

- 3. Harvard T.H. Chan School of Public Health, Boston, MA, United States.*
- 4. College of Health Sciences, University of California, Irvine, Irvine, CA, United States.*

**Abstract:** Background: Natural vegetation, or greenness, has been shown to promote physical activity, social engagement, and cognitive restoration, and reduce ambient pollutants. Greenness was also associated with lower rates of cancer mortality among women. Our objective was to determine if greenness was associated with lower rates of breast cancer mortality. Methods: The Nurses' Health Study II is an ongoing US nationwide prospective cohort study. Participants with Stage I-III breast cancer diagnosed from 1989-2013 were followed until June 2014 for total and breast cancer specific death. The Normalized Difference Vegetation Index (NDVI) is a satellite-based measure quantifying vegetation density within a 1-km area. NDVI estimates were linked to residential addresses. We calculated time-varying cumulative average greenness from diagnosis until the end of follow-up. We performed multivariable Cox proportional hazards models to estimate hazard ratios (HR) and 95% confidence intervals (CI) and used restricted cubic splines to explore non-linear associations. We assessed effect modification by clinical factors, physical activity, population density and region. Results: Among 1,890 breast cancer cases, there were 213 breast cancer deaths and 255 deaths from all causes. Cumulative average greenness was not associated with breast cancer specific mortality (HR for a 0.1-unit increase in NDVI=1.03; 95% CI 0.88, 1.21) or all-cause mortality (HR=1.04; 95% CI 0.90, 1.19). We observed no modification by clinical factors, population density, and physical activity. While patterns in the Midwest and West suggested benefits for those residing in the highest and lowest levels of green space, results were inconclusive given the small number of events within region. Discussion: The benefits of residential greenness exposure may not extend to breast cancer specific mortality. Regional differences in green space may point to environmental and behavioral differences that should be further explored.

## **O04.02.23. Residential Greenness and Mortality in a Prospective Cohort of Oldest-Old Women and Men in China**

John Ji

*John S. Ji<sup>1</sup>, Anna Zhu<sup>1</sup>, Chen Bai<sup>4</sup>, Peter James<sup>2</sup>, Lijing Yan<sup>3</sup>, Yi Zeng<sup>6</sup>, Chih-Da Wu<sup>5</sup>*

- 6. School of Medicine, Duke University, Durham, NC, United States.*

**Abstract:** Background: Exposure to nature, or greenness, may affect health through several pathways, including health-promoting activities and influencing psychological well-being. How greenness affects old-age health vulnerabilities has not been assessed. Objective: We assessed the relationship between residential greenness and its relationship to mortality in an elderly cohort representative of China. Methods: We used the prospective China Longitudinal Health Longevity Survey (CLHLS) cohort to assess the relationship between greenness and mortality. Our exposure was assessed by satellite derived Normalized Difference Vegetation Index (NDVI) in 250m and 1250m radius around residential addresses between 2000 to 2014 in 3839 women and men. We calculated cumulative, contemporaneous, and change of NDVI values over time. We used all-cause mortality, excluding accidental death, as our outcome measurement. Results: The mean age of our study population at baseline was 92 (sd: 7.57) years. Among 3839 subjects totaling 13253 person-years, we observed 3244 deaths during follow up. We used cox-proportional hazard models, adjusted for age, gender, ethnicity, rural/urban residence, geographical region, education years, occupation before age 60, marital status, smoking status, alcohol consumption, exercise, financial support, and co-residence status. Compared to the lowest quartile of contemporaneous NDVI values, those in the highest quartile had a HR of 0.82 (95% CI: 0.74 - 0.92) for the 250-m radius, and 0.76 (95% CI: 0.69 - 0.85) for the 1250-m radius. No significant effects were not found for cumulative NDVI measurement. Conclusion: In this prospective cohort of older adults, we observed that living in areas with higher levels of greenness was associated with lower levels of mortality. Furthermore, those living in areas of increasing greenness over time also saw a reduction in mortality. Our research has policy implications for eco-civilization and preparing for aging societies in China.

## **004.02.24. The Association between Long-Term Neighborhood Greenness and Lethal Prostate Cancer in a Prospective Cohort Study of Male Health Professionals in the United States**

**Abstract:** Background Emerging literature documents health benefits of natural environments. We studied the association between neighborhood greenness and 26-year incidence of lethal prostate cancer (CaP), effect modification by address type (home or workplace), and mediation by vigorous physical activity. Methods Participants in the Health Professionals Follow-up Study, a nationwide prospective cohort, were followed from 1986 to 2012. We excluded those with history of CaP or missing address. Lethal CaP was defined by metastasis or CaP death. Neighborhood greenness was measured using normalized difference vegetation index (NDVI) with 1km<sup>2</sup> resolution. Participants were assigned NDVI corresponding to their address at start of follow-up, taking averages over four seasonal measures. NDVI was modeled using quintiles. Data were analyzed using sequentially adjusted Cox regression models: 1) age, calendar year, race, family history, smoking, BMI at 21, PSA screening, census median income and home value, walkability index; 2) vigorous and non-vigorous physical activity, current BMI. Results 46,494 participants met eligibility criteria. Men in greener neighborhoods at baseline experienced lower rates of lethal CaP (model 1: Q2 v Q1, aHR: 0.84, 95% CI: 0.67-1.05; Q3 aHR: 0.86, 95% CI: 0.69-1.07; Q4 aHR: 0.77, 95% CI: 0.61-0.97; Q5 aHR: 0.86, 95% CI: 0.69-1.09, ptrend=0.11). Protective associations were strongest among men (39%) reporting work addresses (Q2 v Q1, aHR: 0.73, 95% CI: 0.51-1.02; Q3 aHR: 0.61, 95% CI: 0.42-0.89; Q4 aHR: 0.55, 95% CI: 0.37-0.83; Q5 aHR: 0.65, 95% CI: 0.42-1.00, ptrend=0.0005). Further adjustment for mediators (model 2) did not change effect estimates. Conclusions Our findings suggest a protective association between neighborhood greenness and lethal CaP independent of physical activity, though overall results were not statistically significant. Stronger associations at work suggest benefits may arise from passive rather than active engagement with nature.

## 004.02E. Neurodevelopment in Children

### **004.02.25. Postnatal Exposure to Secondhand Smoke Measured with Urinary Cotinine and Neurodevelopment at 36 Months after Considering Outdoor Fine Particle (PM2.5)**

**Abstract:** Background/Objective Neurodevelopment of infants have been associated with exposure to secondhand smoke (SHS) and air pollution (AP), respectively. There has been very few previous studies of combined effect of AP and SHS on early neurodevelopment. We aim to investigate the combined effect of postnatal AP and SHS exposure on neurodevelopment of infants at 36 months of age. Methods This study is a part of the Mothers and Children Environmental Health (MOCEH) study, a Korean multi-center prospective birth cohort study initiated in 2006. We measured infants' urinary cotinine at 24 months and 36 months of age to represent postnatal SHS exposure. PM2.5 (particulate matter <2.5 in diameter) level from conception was modelled using the Community Multiscale Air Quality Modeling. The exposure estimations of PM2.5 of each subject were assigned in district level. Infant's mental developmental index (MDI) and psychomotor developmental index (PDI) were measured using the Bayley Scales of Infant Development at 36 months of age. General linear model was used to assess the relationship between combined exposure of PM2.5 and SHS and neurodevelopment. Results MDI score of 36 months aged infants was marginally associated with log-transformed urinary cotinine level at 24 months [ $\beta = -1.94$ , 95%confidence interval (CI): -3.92, 0.04] after adjusting for log-transformed urinary cotinine level at 36 months and PM2.5 level after birth. The association was statistically significant when the effect of PM2.5 level at early pregnancy was considered,  $\beta = -2.02$  (95%CI: -4.01, -0.03). The effect was pronounced in the metropolitan city,  $\beta = -7.92$  (95%CI: -13.15, -2.70). No association was found in PDI score. Conclusions These findings suggest that infants' postnatal exposure to SHS combined with exposure to PM2.5 may result in delayed neurodevelopment in early childhood. Therefore, we should take care of both indoor and outdoor air pollution with regards to the neurodevelopment of infants.

## **O04.02.26. Prenatal Exposure to Bisphenol A and Childhood Neurodevelopment in Shandong, China**

**Abstract:** Background: Experimental and epidemiological studies suggest that prenatal exposure to Bisphenol A (BPA) may interfere with children neurodevelopment. However, current evidence was inconsistent and relevant study from China is limited. Methods: Based on a cohort in northern China, BPA concentrations were measured among 506 pregnant women and neurodevelopment was assessed using the Gesell Development Schedules for their children at 12 months (n=368) and 24 months (n=296). Linear regression and generalized linear models were used to analyze the association between prenatal BPA exposure and children's developmental quotients (DQs). Results: The median of maternal BPA concentrations were 0.48ug/L or 1.05ug/g creatinine. Prenatal BPA levels were adversely associated with children's DQ scores at 12 months of age, with a 10-fold increase in prenatal BPA levels correlated to 1.43-point decrease in adaptive domain DQs (95%CI: -2.30 to -0.56, p=0.001). When stratified by child gender, prenatal BPA concentrations were adversely associated with the DQs on adaptive domain among boys and the DQs on adaptive domain and social domain among girls. No association was found between prenatal BPA exposure and children's DQs at 24 months of age. Conclusion: Based a Chinese population, we demonstrated potential impacts of prenatal BPA exposure on neurodevelopment for children at 12 months of age, which differ between child age and gender.

## 004.02.27. Sensitive Windows of Manganese Exposure and Frontal Cortex Function in Adolescents

**Abstract:** Introduction: Prior studies have reported Mn-associated decrements in IQ, a composite score computed from subtests. We examined patterns of IQ subtest scores to generate hypotheses about the underlying structural changes in the brain that may be produced by early life Mn exposure among adolescents living near ferromanganese industry. Methods: We analyzed deciduous teeth from 190 Italian children ages 10-14 years. Mn was measured in the tooth matrix to represent prenatal, postnatal (0-1 year) and childhood (~1-6 years) exposure periods. Neuropsychologists administered the Wechsler Intelligence Scale for Children, 3rd edition. Multivariable linear regression and generalized additive models were used to estimate adjusted associations between ln-tooth Mn and scores on seven subtests: Arithmetic, Comprehension, Information, Similarities, Vocabulary, Digits forward and Digits backward. Results: We observed varied patterns of adjusted associations between tooth Mn and subtest performance, depending on the window of exposure. Overall, subtests associated with Mn across exposure windows measure memory, problem solving and attention, suggesting frontal system and hippocampal involvement. We found inverted U-shaped associations between prenatal Mn and Arithmetic, Comprehension, Information and Digits forward ( $p_{\text{gam}}=0.18-0.39$ ). Early postnatal Mn was associated with better performance on Arithmetic ( $\beta=0.27$  (95%CI=-0.63, 1.17)), Information ( $\beta=0.35$  (95%CI=-0.42, 1.13)), and Digits forward ( $\beta=0.51$  (95%CI=0.21, 0.81)). However, childhood Mn was associated with lower Information scores ( $\beta=-0.35$  (95%CI=-1.11, 0.41)) and non-linearly associated with Digits forward ( $p_{\text{gam}}=0.06$ ). In these data, the shape of the Mn-subtest relationship was dependent on exposure timing. Conclusion: Our results suggest that frontal cortex function may be sensitive to Mn exposure. Higher Mn may be toxic in childhood, potentially identifying a window for intervention implementation.

## **004.02.28. The Association between Prenatal Selenium-Related DNA Methylation Modifications in Placenta and Newborn Neurobehavioral Development: An Epigenome-Wide Study of Two U.S. Birth Cohorts**

**Abstract: Background/Aim:** As a micronutrient, selenium (Se) levels in pregnancy have been linked with the neurobehavioral development of the offspring. DNA methylation is a potential mediator of the effect of Se on neurobehavioral development; however, very few studies have investigated the role of DNA methylation in relation to prenatal Se and child neurobehavior. We aimed to investigate the associations between placental Se and epigenome-wide DNA methylation in two U.S. cohorts and to assess the association between Se-related DNA methylation modifications and children's neurobehavioral development. **Methods:** We measured placental Se concentration of 343 newborns enrolled in the New Hampshire Birth Cohort Study and of 141 infants in the Rhode Island Child Health Study. Genome-wide placental DNA methylation was measured by HumanMethylation450 Bead Chip, and the newborn neurobehavioral development was assessed by the NICU Network Neurobehavioral Scales. We meta-analyzed the associations between placental Se concentration and DNA methylation in each cohort, adjusting for confounders ( $P < 1 \times 10^{-5}$ ). We also fit multiple linear regression to assess the associations between DNA methylation and newborn neurobehavioral development. **Results:** We identified 25 Se-related differentially methylated CpG sites. 18 of the 25 CpG sites were positively associated with placental Se concentration. Among the 18 CpG sites, increased DNA methylation of cg19730691 (OR [95% Confidence Interval, CI] = 0.92 [0.86, 1.00],  $P = 0.05$ ) and cg09674502 (OR [95%CI] = 0.89 [0.81 0.99],  $P = 0.03$ ) were also associated with lower risk of high-level hypertonic responses of infants. The nearest genes to the cg19730691 and cg09674502 are TBX15 and GFI1. **Conclusions:** The Se-related increase of TBX15 and GFI1 DNA methylation were associated with beneficial motor development in infants. Future work will assess the relationship of the identified CpG sites methylation levels with childhood motor development.

## **004.02.29. Neonatal Vitamin D Status in Relation to Autism Spectrum Disorder and Developmental Delay in the Charge Case-Control Study**

Rebecca Schmidt

*Rebecca J. Schmidt<sup>1</sup>, Qiaojuan Niu<sup>2</sup>, Darryl Eyles<sup>3</sup>, Robin Hansen<sup>4</sup>, Ana-Maria Iosif<sup>1</sup>*

**Abstract:** Background Vitamin D is essential for proper neurodevelopment and cognitive and behavioral function. We examined newborn vitamin D in relation to later diagnosis of autism spectrum disorder (ASD) or developmental delay (DD). Methods Children aged 24-60 months enrolled in the population-based CHARGE case-control study were clinically confirmed to have ASD (n=373), DD (n=136), or typical development (TD, n=234) at the MIND Institute (Sacramento, CA) using standardized assessments. Total 25-hydroxyvitamin D (25OHD) was measured using sensitive isotope dilution LC/MS/MS in archived dried blood spots collected for the California Department of Public Health's Newborn Screening Program. Associations between 20 nmol/L 25OHD change and ASD and DD were assessed using unconditional multivariate polynomial logistic regression; associations between 25OHD and Mullen Scales of Early Learning (MSEL) and Vineland Adaptive Behavior Scales (VABS) scores were assessed using multivariate linear regression. Effect modification was examined using stratified models and interaction product terms. Results Neonatal 25OHD was associated with significantly reduced ASD only in females (aOR=0.66; 95% CI: 0.48, 0.91,  $p=0.01$ ). 25OHD was significantly associated with reduced DD before (OR=0.84, 95% CI: 0.73, 0.97) but not after adjustment for maternal pre-pregnancy body mass index, prenatal vitamin intake, and education, and child race/ethnicity (aOR=0.91, 95% CI: 0.78, 1.06). Similarly, MSEL and VABS were significantly associated before, but not after adjustment for several factors that could contribute to vitamin D status. Significant interaction by race/ethnicity was observed ( $p=0.02$ ), with an association between 25OHD and DD only in non-Hispanic white children (aOR=0.76; 95% CI: 0.61, 0.95). Conclusions This study provides evidence that newborn vitamin D could be associated with ASD in females and with DD in non-Hispanic white children. Future studies should investigate genetic interactions.

## **O04.02.30. Maternal Thyroid Anomalies and Risk of Autism Spectrum Disorders**

Ran Rotem

*Ran Rotem<sup>1</sup>, Gabriel Chodick<sup>3</sup>, Michael Davidovitch<sup>2</sup>, Gideon Koren<sup>3</sup>, Varda Shalev<sup>3</sup>, Vy Nguyen<sup>1</sup>, Brent A. Coull<sup>1</sup>, Russ Hauser<sup>1</sup>, Marc Weisskopf<sup>1</sup>*

- 1. Harvard School of Public Health, Boston, MA, United States.*
- 2. Child Development, Maccabi Healthcare Services, Tel Aviv, Israel.*
- 3. Maccabi Institute for Research and Innovation, Tel Aviv, Israel.*

**Abstract:** Background Thyroid hormones play pivotal roles in neurodevelopment. The fetus is dependent on maternal supply of thyroid hormones throughout gestation, suggesting that factors influencing maternal thyroid function may also relate to adverse neurodevelopmental effects in progeny. Impaired thyroid homeostasis has been linked with exposure to several environmental toxicants, yet consequences in the offspring remain unclear. We evaluated the risk of Autism Spectrum Disorders (ASD) in children born to mothers with thyroid anomalies, and the relation between gestational maternal thyroid levels and ASD risk. Methods The study included 436,188 singletons born in 1999-2013 in a large Israeli health fund. Data on ASD diagnoses, maternal thyroid conditions, drug dispensing and lab results were obtained through 2017. Mothers with thyroid conditions were identified through ICD9 codes with subsequent validation through review of drug dispensing data and lab results. ASD cases were identified through ICD9 codes and validated through review of medical records. Analyses were performed using generalized estimating equation (GEE) and general additive logistic regression models using penalized splines. Results Mothers who had ever experienced hypothyroidism were at a higher risk of having a child with ASD compared to women without thyroid conditions (aOR=1.28, 95% C.I.:1.13-1.44). Stratified analysis based on time of first diagnosis indicated elevated risk estimates for diagnoses initially recorded both before and after the delivery date. Analysis of first-trimester TSH levels suggested a linear association with ASD risk at moderately elevated levels. Use of thyroid replacement medications during pregnancy did not mitigate the observed effects. Conclusions The results suggest that factors which influence thyroid metabolism could also play a role in the etiology of ASD. Environmental triggers known to influence thyroid function should be carefully evaluated for their neurodevelopmental effects.

## 004.02F. New Methods, Models and Tools in Chemical Exposure Estimation

### **004.02.31. A New Analysis and Visualization Tool to Identify Chemical Exposure Disparities by Demographic Traits**

Vy Nguyen

*Vy K. Nguyen<sup>1</sup>, Justin Colacino<sup>2</sup>, Olivier Jolliet<sup>2</sup>*

*1. Department of Computational Medicines & Bioinformatics, University of Michigan, Ann Arbor, MI, United States.*

*2. Environmental Health Sciences, University of Michigan, Ann Arbor, MI, United States.*

**Abstract:** Variations in chemical exposure by demographic traits have been well studied individually for specific chemical classes but are not systematically studied for a wide range of chemicals to contrast the influence of demographic traits on chemical exposure patterns. This study aims to develop a new analysis and visualization tool that enables us to analyze and compare exposure patterns in the US Population 1999-2014 for a large number of traits and chemicals by using the National Health and Nutrition Examination Survey (NHANES) of 229 chemical biomarker concentrations measured in 74,942 participants. We conducted a series of multiple regression models with the chemical biomarker levels as the outcome variable and the main predictors as age, sex, ethnicity, smoking behaviors, and poverty income ratio while adjusting for urinary flow and study years. We developed a visualization tool known as the Alphabet Soup Plot that displays the regression coefficient of each inherent trait for each chemical biomarker and identified widespread differences in chemical biomarker levels by different populations. For most phthalates, there is little to no difference in chemical biomarker levels by race with the exception of mono-ethyl phthalate (used in cosmetics), which is shown to be on average 53%, 103%, and 74% higher in Mexican, Other Hispanic, and Non-Hispanic Black participants respectively than in Non-Hispanic White participants. PFOS and PFHS are shown to be of higher concentrations in Non-Hispanic White participants compared to Mexican and Other Hispanic participants by over 20% and are also shown to be higher in individuals of high socioeconomic status by over 27%. Development of this visualization tool enables us to comprehensively quantify the influence of several inherent traits on multiple chemical exposure patterns and to identify which combination of chemicals and populations should be prioritized for further toxicological evaluation and targeted health interventions.

## **O04.02.32. Using Sheds-S/D Model to Estimate Soil and Dust Ingestion Rates for Adults**

Heidi Hubbard

*Heidi Hubbard<sup>1</sup>, Graham Glen<sup>1</sup>, Jonathan Cohen<sup>1</sup>, Nicolle S. Tulve<sup>3</sup>, Linda Phillips<sup>3</sup>, Kent Thomas<sup>3</sup>, Jackie Moya<sup>3</sup>, Haluk Ozkaynak<sup>2</sup>*

- 2. Consultant, Laguna Woods, CA, United States.*
- 3. US EPA, Durham, NC, United States.*

**Abstract:** Soil and dust ingestion is the primary pathway for environmental exposure to some pollutants. As is the case with children, incidental soil and dust ingestion rates for adults are dependent on the amount of time they contact soil, personal hygiene, and the dustiness of the indoor environment. However, there are little data on adult dust and soil ingestion rates. Here we used the Stochastic Human Exposure and Dose Simulation Soil and Dust (SHEDS-S/D) model to estimate distributions of soil and dust ingestion rates for adults across a range of hobbies and activities that would drive their soil and dust contact. Adults in the population were modeled in four groups: baseline/typical adult; moderate soil contact (e.g., a hobbyist gardener); high soil contact representative of occupational exposure (e.g., agricultural workers); and high dust contact approximating an individual who spends appreciable time in a particularly dusty environment, such as a building undergoing renovation. For SHEDS-S/D model runs we developed new soil adherence factors and new distributions of indoor dust loadings representative of renovation scenarios. Also, new model parameters were developed for adults on: The area of hand mouthed; frequency of hand-to-mouth contact; and the hand contact ratio hand contact with dust or soil. Results showed that annual average adult soil ingestion rates could range from 8 to over 100 mg/day. Moreover, high-dust environments could increase dust intake by a factor of 4. Season-specific runs showed considerable differences between the summer and winter soil and dust ingestion rates; summer values being the highest and winter values the lowest. Sensitivity analyses showed the key drivers of predicted exposures to be carpet dust loading; soil adherence; and variables describing hand-to-mouth, soil and dust contact values. These results identify key data limitations for focusing future research activities to obtain robust soil and dust ingestion rates for adults.

### **O04.02.33. Using Geospatial Methods to Quantify the Co-Dispersion of Mercury Sources and Exposures in River Otter (*Lontra Canadensis*) for Risk Prediction**

Kristin Eccles

*Kristin Eccles<sup>1</sup>, Philippe Thomas<sup>2</sup>, Laurie Chan<sup>1</sup>*

*1. University of Ottawa, Ottawa, ON, Canada.*

*2. Environment and Climate Change Canada, Ottawa, ON, Canada.*

Abstract: Mercury is an environmental contaminant of concern due to the established effects of methylated mercury (MeHg) on neurological functioning. Sentinel species such as the river otter (*Lontra canadensis*) are commonly used to monitor environmental mercury concentrations. Fur mercury has proven to be a reliable and cost-effective measure of exposure to MeHg in river otters and is a good proxy for assessing environmental mercury concentrations. A total of 311 geolocated fur samples were obtained from wildlife biomonitoring programs at Environment and Climate Change Canada and from the North American Fur Auction. These samples represent 131 unique locations throughout Canada collected between 2013 and 2016. Total mercury (THg) was measured on a MA-3000. Clustering of high THg was assessed using Getis and Ord's  $G_i^*$ . The association between fur THg and mercury sources was assessed using linear regression modelling alongside spatial regression methods such as geographically weighted regression. A cluster of low fur THg concentrations was observed in Alberta, and clusters of high fur THg concentrations were observed in northeastern Ontario, New Brunswick, and Nova Scotia. There is a statistically significant ( $p < 0.05$ ) negative relationship between fur THg and proximity to dam reservoir water, and pH of soil. There was also a statistically significant interaction between proximity to dam reservoir water and the pH of the soil. Otters that live closer to the reservoir water of dams have higher fur THg concentrations. This effect is enhanced if the soil pH surrounding the reservoir is also low. Using a geographically weighted regression these variables explain up to 35% of the variance. Results from this research are important for assessing the impact of future hydroelectric dam development on aquatic ecosystems. This research also further supports the use of river otter fur as a biomonitoring tool for environmental mercury exposure.

#### **O04.02.34. INLA-SPDE Models to Predict the Spatial Distribution of Beta-Hexachlorocyclohexane Haematic Levels in a Heavily Polluted Area**

Matteo Scortichini

*Matteo Scortichini<sup>1</sup>, Paola Michelozzi<sup>1</sup>, Silvia Narduzzi<sup>1</sup>, Daniela Porta<sup>1</sup>, Daniela D'Ippoliti<sup>1</sup>, Marina Davoli<sup>1</sup>, Michela Leone<sup>1</sup>*

*1. Department of Epidemiology of Lazio Regional Health Service, Rome, Italy.*

**Abstract:** Introduction the Sacco River Valley has been characterized over the years by the presence of several industrial plants. In 2006 it was discovered that livestock were contaminated by beta-hexachlorocyclohexane ( $\beta$ -HCH) and two biomonitoring campaigns were performed to assess the human burden. The aim of the study is to estimate the spatial distribution of  $\beta$ -HCH hematic levels in the study area as to use it in future studies on the whole resident population. Data and Methods Between 2010 and 2015 740 subjects were randomly sampled from the resident population and blood samples were collected. Every subject was georeferenced by residence address and considered as a "monitoring site". An Integrated Nested Laplace Approximation (INLA) model combined with Stochastic Partial Differential Equation (SPDE) was run to predict the  $\beta$ -HCH levels. This approach allows Bayesian inference when a spatial process defined over a continuous domain is involved. In the model age, sex, latitude, longitude, altitude and distance from the Sacco river (considered as the main driver of contamination) were also fitted as predictors. Results After excluding subjects spatially isolated, the model was run on 703 observations. A significant relationship was observed between age and the log-transformed  $\beta$ -HCH (posterior mean for 1 year increase: 0.047), higher levels were estimated in women. A negative relationship was found for distance from the river (-0.020 for 100m increase in the distance), while the other predictors had no effect. We validated the model by running a 10-fold Cross-Validation, with a correlation index between observed and predicted equal to 0.77. Conclusions This is the first study using blood sample measures to estimate the spatial distribution of  $\beta$ -HCH. Although strong assumptions were made in order to consider subjects as monitoring sites, this kind of analysis would allow to estimate the effect of  $\beta$ -HCH not only on this sampled population, but also on the cohort of all residents.

## **O04.02.35. Modeling Exposure Reduction for Personal Level Interventions**

Miranda Loh

*Miranda Loh<sup>1</sup>, Chun Lin<sup>2</sup>, John Cherrie<sup>1</sup>, Paul Wilkinson<sup>3</sup>*

- 1. Institute of Occupational Medicine, Edinburgh, United Kingdom.*

- 3. London School of Hygiene and Tropical Medicine, London, United Kingdom.*

Abstract: Through the APIC-ESTEE (Air Pollution Impacts on Cardiopulmonary Disease in Beijing: An integrated study of Exposure Science, Toxicogenomics and Environmental Epidemiology) project, we have developed a model for the reduction of personal exposures to air pollution to assess the health impacts of interventions such as face mask wearing and use of indoor air purifiers. The model accounts for population level time activity patterns and micro-environmental concentrations. A preliminary analysis for Beijing used data on time activity patterns based on Chinese exposure factors; indoor and outdoor fine particulate (PM<sub>2.5</sub>) concentrations came from residential home studies, a study of public indoor environments, and a feasibility personal monitoring study. In-transit concentrations were estimated as 110% of ambient concentrations. Three intervention scenarios were modelled - wearing a highly effective or a poorly effective facemask whenever a person is outdoors or in transit and use of an air purifier in the home environment. The effects of these interventions were modelled assuming 'average' (84 µg/m<sup>3</sup>) and high (396 µg/m<sup>3</sup>) outdoor PM<sub>2.5</sub> concentrations. Data for potential exposure reduction for the face mask scenario came from a study of total inward leakage in a volunteer trial with diesel exhaust exposure. Data for the air purifier scenario came from a literature review. Use of a highly effective mask reduced 24-hr average personal exposure by 27% over the baseline scenario of no intervention, while the air purifier reduced exposure by 29% for the average ambient condition. For the high ambient concentration scenario, the highly effective mask reduced exposure by 26% compared to 25% for the air purifier. With a poorly effective mask, the personal exposure reduction under average and high ambient concentrations was 11%. The model will be further developed in a probabilistic form for modelling population level exposure interventions and health impacts.

## **O04.02.36. Ethical Considerations in Modeling and Tools for Measuring Exposure**

Erin Haynes

*Erin N. Haynes<sup>1</sup>*

*1. Environmental Health, University of Cincinnati, Cincinnati, OH, United States.*

Abstract: Developing methods and modeling strategies to estimate potential chemical exposure in populations can provide powerful tools for identifying high-risk communities, generating novel hypotheses, and prioritizing mitigation efforts. Although a potentially powerful tool several ethical issues relating to the methods employed should be considered. What is the quality and quantity of the data used in the modeling tools (i.e., how many samples and how were they collected and processed to assure quality)? How are the models validated? How is the location of human participant data shared, either in visualization tools or with other researchers? When location is used in geospatial modeling when should informed consent be obtained. What is the role of the community in determining how their community is represented and how and who in the community is involved in understanding the modelled data? If human samples were used in the development of the models, such as urine or blood biomarkers, what is the responsibility of the researcher to report the findings back to the participants? These large environmental datasets could be enhanced by community collected data or citizen science. What is the role of citizen science in large-scale environmental data collection used for modeling? What is the obligation of the scientist to use these data to promote public health action? These questions will be used as a basis for engagement in discussion about the ethical aspects of exposure assessment.

## 004.02G. PFAS and Other Health Outcomes

### **004.02.37. Perfluoroalkyl Substances (PFASs) and Liver Inflammation and Fibrosis in Children with Nonalcoholic Fatty Liver Disease (NAFLD)**

Ran Jin

*Ran Jin<sup>1</sup>, Miriam Vos<sup>2</sup>, Douglas I. Walker<sup>3</sup>, Catherine Cioffi<sup>2</sup>, Nicola Santoro<sup>4</sup>, Dean Jones<sup>3</sup>, Rob McConnell<sup>1</sup>, Leda Chatzi<sup>1</sup>*

**Abstract:** Background: Perfluoroalkyl substances (PFASs) cause liver toxicity in rodents and might contribute to the increased prevalence of NAFLD. Children appear to have higher body burden of PFASs and a more progressive form of NAFLD; however, no previous studies have examined effects of PFASs on liver histology, the gold standard for NAFLD assessment. Methods: Concentrations of perfluorooctanoic acid (PFOA), perfluorooctane sulfonate (PFOS) and perfluorohexane sulfonic acid (PFHxS) were quantified in serum of 70 children (7-19 years of age) with biopsy-proven NAFLD, and their associations with liver histological features were examined using multinomial logistic regression models with adjustments for age, sex, ethnicity and BMI Z score. Liver histological features, including grade of steatosis (0-3), lobular inflammation (0-3), portal inflammation (0-2) and fibrosis stage (0-4), were scored according to the NASH Clinical Research Network scoring system. 'Liver inflammation score' was calculated as sum of scores for lobular inflammation and portal inflammation. Results: NAFLD patients were mostly boys (71.4%) and Hispanics (51.4%). The median and interquartile range (IQR) of serum PFOA, PFOS and PFHxS concentrations were 3.42 (1.58), 3.67 (4.48) and 1.53 (3.17) ng/ml, respectively. The odds of having moderate-to-severe inflammation (score >1) compared with no inflammation (score =0) increased with each IQR increase of PFHxS (OR: 3.38, 95% CI: 1.04-10.9). Similarly, the odds of having significant fibrosis (score ≥2) compared to no fibrosis (score =0) increased by 3.95 (95% CI: 1.23-12.7) with each IQR increase of PFHxS. No statistically significant associations of PFOA and PFOS levels with severity of steatosis, inflammation or fibrosis were observed. Conclusions: PFHxS exposure was associated with severity of liver inflammation and fibrosis in children with NAFLD.

#### **O04.02.38. Prenatal Exposure to PFAS and Evaluation of Child Attentional Function at 4-6 Years of Age: The INMA Study, Spain**

**Abstract:** Background. Few studies have assessed the possible association between prenatal exposure to perfluoroalkyl substances (PFAS) and attentional function. We aimed to study such an association during preschool years. Methods. The study population was 921 mother-child pairs (recruitment period: 2003-08), from the Gipuzkoa, Sabadell, and Valencia-INMA cohorts (Spain). PFAS were analyzed in the first-trimester maternal plasma. Attentional function was assessed using the Conners' Kiddie Continuous Performance Test (K-CPT) at 4-6 years of age. We studied three indicators: omission errors (assesses inattention), commission errors (assesses impulsivity), and hit reaction time standard error (HRT-SE, assesses sustained attention). We conducted multivariate regression analyses between log<sub>2</sub>-transformed PFAS and the outcomes in each cohort and subsequent meta-analysis. We assessed sex effect modification, conducted multi-pollutant analysis, and excluded preterm and small for gestational age newborns. Results. PFHxS, PFOA, PFOS, and PFNA median levels were 0.55, 2.32, 5.91, and 0.63 ng/mL, respectively. We did not find any association between PFAS and child attentional function for the whole population. Although a non-clear differential effect between sexes (*p*-interaction>0.05) was found, higher estimates of the association between commission errors and the four PFAS were shown in girls, reaching statistical significance for PFNA (Beta: 1.3 [95%CI: 0.02, 2.05] associated with a 2-fold increase in PFNA levels). Estimates did not differ markedly in other sensitivity analyses. Conclusions. Results did not suggest an association between maternal PFAS and attention in preschool children. However, more research is needed to analyze this relationship in other populations at the same or older ages, and to assess a possible association in girls. Funding. #### **004.02.39. Perfluoroalkyl Substances (PFAS) Blood Levels and Health Outcomes in Residents Following Contamination of the Community Water Supply in Paulsboro, New Jersey**

Judith Graber

*Judith Graber<sup>2</sup>, Cora Alexander<sup>1</sup>, Robert Laumbach<sup>1</sup>, Zhongyuan Mi<sup>1</sup>, Kathleen Black<sup>1</sup>, Panos Georgopoulos<sup>1</sup>, Clifford Weisel<sup>1</sup>*

*1. EOHSI, Rutgers University, Piscataway, NJ, United States.*

*2. School of Public Health, Department of Epidemiology, Rutgers The State University of New Jersey, Piscataway, NJ, United States.*

**Abstract:** Background: Perfluoroalkyl substances (PFAS) are chemicals of emerging concern. A PFAS, Perfluorononanoic Acid (PFNA), was detected in the community water supply (CWS) of Paulsboro, NJ at a ten-fold higher level than the NJ groundwater criterion (10 ng/L). In 2014, the CWS was filtered to remove PFAS. Little is known about the health effects of PFNA, concerns include disruption of immune response; disruption of cholesterol homeostasis; and adverse liver, thyroid and/or reproductive system effects. Methods: A class-action lawsuit awarded Paulsboro residents a blood test for 11 PFAS. Consenting participants provided those blood test results and were surveyed about demographic and health information. The geometric means of PFAS serum levels were compared to those of the 2013-2014 NHANES. Linear regression was used to assess associations between PFNA levels and demographics. Logistic regression was used to assess associations between PFAS serum levels and self-reported health outcomes (high cholesterol; circulatory issues, CVD, neurological diagnoses, and pregnancy outcomes). Results: Four PFAS were detected in >25% of 194 participants: perfluorohexane sulfonate (PFHxS; 70.9%), perfluorooctane sulfonate (PFOS; 96.9%), perfluorononanoic acid (PFNA; 97.9%), and, perfluorooctanoic acid (PFOA; 98.5%). PFOA and PFNA serum concentrations were significantly higher among study than NHANES participants (PFNA: 0.91 ng/L, 95 %CI: 0.87, 0.96, vs. 3.50 ng/L 95 %CI: 3.04, 4 .04; PFOA: 2.08 ng/L 95 %CI: 1.91, 2.26 vs. 3.03 ng/L, 95 % CI: 2.70, 3.40). Among the 105 participants with health data, PFNA blood levels were significantly associated with and high cholesterol (odds ratio 1.14, 95% CI 1.02, 1.29). No other significant associations were observed between PFAS and health outcomes. Discussion/Conclusion: PFNA levels in Paulsboro residents exceeded those in the general US population. Further research is warranted to explore associations between PFNA levels and health outcomes.

#### **004.02.40. Breast Cancer Risk and Serum Levels of Per- and Poly-Fluoroalkyl Substances (PFASs): A Case-Control Study Nested in the California Teachers Study**

Peggy Reynolds

*Susan E. Hurley<sup>1</sup>, Debbie Goldberg<sup>1</sup>, Miaomiao Wang<sup>2</sup>, June-Soo Park<sup>2</sup>, Myrto Petreas<sup>2</sup>, Leslie Bernstein<sup>3</sup>, Hoda Anton-Culver<sup>4</sup>, David O. Nelson<sup>1</sup>, Peggy Reynolds<sup>1</sup>*

- 4. Dept Epidemiology, School of Medicine, University of California Irvine, Irvine, CA, United States.*

**Abstract:** Background: Per- and poly- fluoroalkyl substances (PFASs) are a large family of synthetic chemicals, some of which are known mammary gland toxicants and endocrine disruptors. Their potential as human breast carcinogens is unclear. Objective: Our objective was to evaluate the risk of breast cancer associated with serum levels of several PFASs in a nested case-control study within the California Teachers Study (CTS). Methods: Participants were 902 women with invasive breast cancer (cases) and 858 with no such diagnosis (controls) who provided 10 mL of blood and were interviewed about specific exposures between October 2011 and August 2015. Serum PFASs were measured using automated online SPE-HPLC-MS/MS methods. Statistical analyses were conducted for six PFASs with detection frequencies > 95%: PFOA (Perfluorooctanoic acid), PFNA (Perfluorononanoic acid), PFUnDA (Perfluoroundecanoic acid), PFHxS (Perfluorohexane sulfonic acid), PFOS (Perfluorooctane sulfonic acid), MeFOSAA (2-(N-Methyl-perfluorooctane sulfonamido) acetic acid). Unconditional logistic regression models were used to calculate the adjusted odds ratio (OR), estimating breast cancer risk associated with each PFAS. Results: With few exceptions, ORs did not statistically differ from one. ORs were less than one and statistically significant for PFOA ( $p=0.043$ ) and PFUnDA ( $p=0.044$ ) and of borderline statistical significance for PFHxS ( $p=0.060$ ), with little evidence for trend. Conclusion: Overall these findings do not provide evidence that serum PFAS levels measured after diagnosis are related to breast cancer risk in this population of middle-aged or older California women. The few inverse associations found may be due to chance or may be artifacts of study design. Future studies should incorporate information about genetic susceptibility, endogenous estrogen levels, and measurements of PFASs prior to diagnosis.

#### **004.02.41. Concentrations of Endocrine Disruptors in Newborn Dried Blood Spots and Child Behavior**

**Abstract:** Background: Experimental studies suggest that prenatal exposure to endocrine disrupting chemicals interferes with developmental processes in the fetal brain. Yet, evidence is inconclusive. Methods: In a birth cohort (2008-2010, upstate New York), we quantified concentrations of bisphenol A (BPA), perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) in stored newborn dried blood spots using liquid chromatography/tandem mass spectrometry. Mothers reported on children's behavior using the Strength and Difficulties Questionnaire at age 7 (650 singletons and 138 twins). Difficulties in behavior (i.e., emotional, conduct, hyperactivity, and peer problems) and prosocial skills were classified at validated cut-offs. We used logistic regression with generalized estimating equations to estimate the odds of having difficulties per exposure category. Models were adjusted for maternal and child characteristics, e.g., ethnicity, smoking, parity, and pre-pregnancy body mass index (and preterm delivery for BPA). Results: 111 children (12.1%) had behavioral difficulties and 60 (6.5%) had problems in prosocial skills. The median (interquartile range) of PFOS, PFOA, and BPA were 1.74 ng/ml (1.33), 1.12 ng/ml (0.96), and 7.93 ng/ml (10.79), respectively. Higher PFOS levels were associated with increased odds of having behavioral difficulties (OR per SD of log PFOS=1.33, 95%CI: 1.05-1.67). We observed associations between PFOS in the highest relative to the lowest quartile and behavioral difficulties (OR for PFOS<sub>1.14-1.74</sub>=1.73, 95%CI:0.87-3.44; PFOS<sub>1.75-2.47</sub>=1.83, 95%CI:0.93-3.57; and PFOS<sub>>2.47</sub>=2.56, 95%CI:1.34-4.91 compared to PFOS<1.41). Higher PFOA levels were linearly associated with problems in prosocial skills (OR=1.36, 95%CI:1.05-1.76). We found no associations with BPA, nor interactions with sex or plurality. Conclusion: Increasing prenatal exposure to PFOS and PFOA, as reflected in neonatal concentrations, may pose risk for child behavioral difficulties.

## **004.02.42. Concentrations of Endocrine Disrupting Chemicals in Newborn Blood Spots and Early Development, Upstate Kids Study**

Erin Bell

*Erin M. Bell<sup>1</sup>, Edwina Yeung<sup>2</sup>, Wanli Ma<sup>3</sup>, Kurunthachalam Kannan<sup>4</sup>, Akhgar Ghassabian<sup>5</sup>, Rajeshwari Sundaram<sup>2</sup>, Germaine Louis<sup>6</sup>*

**Abstract:** Novel methods for quantifying chemicals in newborn dried bloodspots (NBS) allows researchers to directly measure exposures in children for examining impact on early development at the population level. We quantified three endocrine disrupting chemicals (EDCs) in NBS and assessed their associations with developmental screening results in the Upstate KIDS population-based birth cohort. The study included 2,049 singletons and 1,030 twins who were followed through age 3. The equivalent of one 16-mm circle was collected from stored NBS and measured for bisphenol A (BPA), perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) using high-performance liquid chromatography/tandem mass spectrometry with limits of detection of 0.30, 0.03 and 0.05 ng/mL, respectively. Parents completed 7 Ages and Stages Questionnaires© between 4 and 36 months of age for each child and results were calculated for failing any of five domains (fine and gross motor, communication, personal-social, problem solving). Using generalized linear mixed modeling techniques with log transformed EDCs, we estimated adjusted odds ratios (aOR) and 95% confidence intervals (CI) per standard deviation increase in log-transformed chemical concentrations. A second random intercept was included to account for clustering between twins from the same family. All models were adjusted for maternal age, education, and infertility treatment. The PFOS and PFOA median concentrations were 1.69 ng/ml (IQR: 1.11, 2.40) and 1.08 ng/ml (IQR: 0.67, 1.60), respectively and 7.89 ng/ml (IQR: 3.38, 14.56 ng/ml) for BPA. Among singletons, failing any domain was not associated with PFOS or PFOA (aOR: 0.89; 0.77-1.05 and aOR: 0.93;0.79-1.09 per SD increase in concentrations, respectively) or with BPA (aOR:1.04; 0.89-1.21). Results did not differ for twins. Using direct measures of EDCs in newborn infants, we observed no association with early development through age three.

## 004.02H. Air Pollution Accountability and Quasi Experimental Studies

### **004.02.43. Triggering of ST-Elevation Myocardial Infarction by Particulate Air Pollution Concentrations in Monroe County, New York: Before, During, and After Multiple Air Quality Interventions and Policies - The Rochester Accountability Study**

- 4. Department of Environmental Medicine, University of Rochester Medical Center, Rochester, NY, United States.*

Abstract: Previously, we reported that increased PM concentrations triggered ST elevation myocardial infarction (STEMI), with the largest rate of MI when pollutant mixtures were high in secondary particles. From 2007-2013, several policies were implemented to improve air quality and reduce pollutant emissions nationally and in New York (NY). In Rochester, NY, concentrations of submicron particles, SO<sub>2</sub>, and PM<sub>2.5</sub> and its main component (SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, elemental and primary organic carbon) were substantially lower AFTER these policies were implemented (2014-2016) than BEFORE (2005-2007) and DURING policy implementation (2008-2013). However, secondary organic carbon (SOC) concentrations increased AFTER implementation. Using 921 STEMIs treated at the University of Rochester Medical Center Cardiac Catheterization Laboratory and case-crossover methods, we examined whether the rate of STEMI associated with increased PM<sub>2.5</sub>, ultrafine particles (UFP, <100nm), accumulation mode particles (100-500nm), black carbon (BC), SO<sub>2</sub>, CO, and O<sub>3</sub>, in the previous 1-72 hours, was modified by period (BEFORE, DURING, AFTER), to evaluate whether pollutant compositional changes affected the relative rate of acute cardiovascular events. Interquartile range increases in UFP concentration in the previous 1 and 3 hours were associated with 12% (95% CI = 3%, 22%) and 11% (95% CI = 2%, 22%) increases, respectively, in the rate of STEMI, with similar patterns for BC, CO, and SO<sub>2</sub>. However, each 3702 particles/cm<sup>3</sup> increase in UFP in the previous hour was associated with a larger increased rate of STEMI in the AFTER period (26%; 95% CI=7%, 48%) than the DURING (5%; 95% CI=-12%, 24%) or BEFORE periods (9%; 95% CI=-4%, 23%). There were similar BC and SO<sub>2</sub> patterns. Given the concomitant changes in PM composition, strong oxidants associated with SOC particles and their ability to induce additional oxidative stress may be particularly important with regard to the triggering of acute cardiovascular events.

#### **O04.02.44. The Effect of Environmental Policies and Hospital Visit Rate by Asthma in Seoul, Korea: Quasi-Experimental Study**

Hyomi Kim

*Hyomi Kim<sup>1</sup>, Honghyok Kim<sup>1</sup>, Garam Byun<sup>1</sup>, Yongsoo Choi<sup>1</sup>, Sera Kim<sup>1</sup>, Jong-Tae Lee<sup>1</sup>*

*1. BK21PLUS Program in 'Embodiment: Health-Society Interaction', Department of Public Health Science, Graduate School, Korea University, Seoul, Korea (the Republic of).*

Abstract: In 2005, "The Master Plan for Atmospheric Environment Management in Capital Area" is established to reduce ambient concentration of air pollutants. Based on the plan, environmental policies to reduce emissions of pollutants are enforced in the capital area in 2007. As a result, it shows good performance compare to the planed emission reduction, especially for traffic related sources. Traffic related air pollutants are known as a one of risk factors for asthma. The objective of this study was to evaluate the effect of environmental policies on hospital visit by asthma in Seoul with consideration of hospital visit rates in a reference population (Daejeon), in Korea. We obtained daily hospital visit count for asthma (ICD10: J45) from National Health Insurance Corporation for the period of 2003 to 2011. PM10, NO2 data were obtained from the National Institute of Environmental Research. We used interrupted time-series regression with Poisson distribution to investigate the effect of policies. Daejeon was selected as similar to population characteristics in the Seoul except for the environmental policies. After the enforcement of policies, the reduction of ambient concentration of air pollutants in Seoul ( $\Delta\text{PM}_{10}=-8.59\mu\text{g}/\text{m}^3, \Delta\text{NO}_2=-0.95\text{ppb}$ ) were greater than Daejeon ( $\Delta\text{PM}_{10}=-1.99\mu\text{g}/\text{m}^3, \Delta\text{NO}_2=1.19\text{ppb}$ ). Percent changes in age-standardized hospital visit rates per 100,000 for the period of 2003 to 2006 were 26.26% in Seoul and 13.27% in Daejeon. However, since the policies has been implemented, percent changes were 3.73% in Seoul and 14.39% in Daejeon. Even after adjusting for hospital visit rate in Daejeon, increasing trend of hospital visit by asthma ( $\beta$  of time trend= $6.676\text{e}-5$ ,  $p<.01$ ) was significantly reduced by implementation of the policies ( $\beta$  of time\*policies= $-1.081\text{e}-4$ ,  $p<.001$ ). This study results showed the evidence that the environmental policies introduced in 2007 has a positive impact on both air quality and hospital visit by asthma in Seoul, Korea.

**O04.02.45. Does the Association between Cardiovascular Hospital Admissions and Fine Particle Concentrations Change Before, During, and After Implementation of Multiple Environmental Policies? The New York State Accountability Study**

Wangjian Zhang

*Wangjian Zhang<sup>1</sup>, Shao Lin<sup>1</sup>, Philip Hopke<sup>2</sup>, Sally Thurston<sup>3</sup>, Edwin van Wijngaarden<sup>2</sup>, Daniel Croft<sup>4</sup>, Stefania Squizzato<sup>2</sup>, Mauro Masiol<sup>2</sup>, David Rich<sup>2</sup>*

- 4. Department of Medicine, University of Rochester Medical Center, Rochester, Rochester, NY, United States.*

**Abstract:** Previous studies reported triggering of acute cardiovascular (CV) events by short-term increases in ambient PM<sub>2.5</sub> concentrations. From 2007-2013, policies to improve air quality implemented nationally and across New York (NY), and economic influences, resulted in reduced concentrations of PM<sub>2.5</sub> and other pollutants, but not O<sub>3</sub>, at 6 urban NY monitoring stations. We estimated the rate of CV hospital admissions associated with increased ambient PM<sub>2.5</sub> concentrations in the previous 1-7 days, and evaluated whether they were different BEFORE (2005-2007), DURING (2008-2013), and AFTER policy implementation (2014-2016). Using all hospital admissions with a primary diagnosis of 9 CV disease subtypes, for NY residents living within 15 miles of PM<sub>2.5</sub> monitoring sites in Buffalo, Rochester, Albany, Queens, Bronx, and Manhattan from 2005-2016 (N=1,922,918), the annual CV disease admission rate decreased from BEFORE (15.6/1000 people [‰]) to DURING (13.6‰) to AFTER (11.8‰) implementation. Using a case-crossover design and conditional logistic regression, interquartile range (IQR) increases in PM<sub>2.5</sub> in the previous 0 to 6 days were associated with 0.6%-1.2% increases in the rate of CV admissions (2005-2016). There were similar patterns for cardiac arrhythmia, ischemic stroke, congestive heart failure, ischemic heart disease (IHD), and myocardial infarction (MI). However, the excess rate of IHD admissions associated with each IQR increase in PM<sub>2.5</sub> in the previous 2 days was larger in the AFTER period (2.8%) than in the DURING (0.6%) or BEFORE periods (0.8%), with similar patterns in the previous 1-5 days. Both total CVD and MI, but not other disease groups, followed the same pattern. While pollutant concentrations and CV admission rates decreased AFTER policy implementation, the rates of ischemic heart disease and MI associated with the IQR increases in PM<sub>2.5</sub> increased. Compositional PM changes AFTER implementation may make the same PM<sub>2.5</sub> mass more likely to trigger CV events.

#### **O04.02.46. Air Quality Management Policy and Reduced Mortality Rates in Seoul Metropolitan Area: A Quasi-Experimental Study**

*Changwoo Han<sup>1</sup>, Youn-hee Lim<sup>2</sup>, Yun-Chul Hong<sup>3</sup>*

*1. Department of Preventive Medicine, Seoul National University College of Medicine, Seoul, Korea (the Republic of).*

*2. Institute of Environmental Medicine, Seoul National University Medical Research Center, Seoul, Korea (the Republic of).*

*3. Environmental Health Center, Seoul National University College of Medicine, Seoul, Korea (the Republic of).*

**Abstract:** Background: The air quality management policy was introduced in Seoul and Incheon metropolitan cities in the Republic of Korea, from 2005 to 2014. Despite particulate matter concentrations decreasing after policy implementation, the consequent health benefits have not been evaluated. Objectives: We evaluated the effects of the air quality management policy on mortality rates in Seoul and Incheon. Methods: Using interrupted time series analysis with a generalized Poisson regression model, we compared daily average mortality rates before (baseline, 2004-2005) and after (2006-2007, 2008-2009, 2010-2011, 2012-2013) the policy implementation. To account for the long term mortality trends, we weighted daily mortality rate of Seoul and Incheon with daily mortality rate of Daejeon (another metropolitan city with no air quality management policy implemented). Results: Decline in the particulate matter concentration was greater in Seoul and Incheon than in Daejeon. After adjusting for potential confounders, there were 8% decrease in cardiovascular disease mortality rates and 10% decrease in cerebrovascular disease mortality rates in Seoul in 2012-2013 compared to the baseline period. In Incheon, an 8% reduction in cerebrovascular disease mortality rates in 2012-2013 was reported. There was no change in mortality rates due to external causes or other causes of deaths excluding cardiovascular and pulmonary disease after policy implementation. Conclusions: Our study suggests that the air quality management policy was effective in reducing mortality rates in Seoul and Incheon.

#### **O04.02.47. A Quantitative Analysis of Health Risk Perception, Exposure Levels, and WTP/WTA of PM2.5 during the 2014 Nanjing Youth Olympic Games**

Lei Huang

*Lei Huang<sup>1</sup>*

*1. School of the Environment, Nanjing University, Nanjing, Jiangsu, China.*

Abstract: Local governments in China regularly implement authoritative short-term emission control measures to improve air quality during important sporting events. As a condition for hosting the 2014 Youth Olympic Games (YOG), the local government of Nanjing agreed to temporarily and substantially improve air quality in Nanjing for the YOG. Regression analysis, Spearman correlation analysis, chi-square test, and the Contingent Valuation method were used to explore the effects of robust, short-term air pollution control measures on 1) health risk perception, 2) daily exposure to PM2.5, 3) health risk acceptance levels, and 4) willingness to pay/accept (WTP/WTA) for eliminating health risk level. Post-implementation, the respondents' health risk perception levels presented the following changes: during the YOG, the respondents perceived the lowest effects of haze pollution while after the YOG, they perceived the highest effects. The changes in health risk acceptance levels showed the same tendency, demonstrating that people were more sensitive to PM2.5 exposure and held higher standards for air quality after the government implemented the emission control measures. Meanwhile, after the YOG, the respondents asked for the most economic compensation and their WTP for risk reduction also reached the highest level. This study reveals the need to 1) raise public awareness about the health risks of air pollution, 2) protect those populations most exposed to high levels of PM2.5, and 3) take more effective long-term measures to meet local residents' demands for improved air quality.

#### 004.02.48. Impact of Improved Air Quality and Genetics on Aging Lungs

Tamara Schikowski

**Abstract:** Introduction: The beneficial effect of a reduction of outdoor air pollution on lung function in the elderly remains unclear, and scarce data exist regarding the modifying effect of genetics. We examined associations between decline in air pollutants (nitrogen oxides [NO<sub>2</sub>, NO<sub>x</sub>], particulate matter [PM<sub>2.5</sub>, PM<sub>10</sub>] exposure) and lung function measures and their interaction with lung function related risk alleles in elderly German women. Methods: Data were analyzed from the SALIA study (Study on the influence of Air pollution on Lung function, Inflammation and Aging; N=601). Spirometry (FEV<sub>1</sub>, FVC) was conducted at baseline (1985-1994; all women 55 years of age), first follow-up (2007-2010) and second follow-up (2012-2013). Air pollution concentrations at home addresses were determined for each time of investigation using land-use regression models and extrapolation procedures. GLI (Global Lung Initiative) age and height standardized z-scores were calculated. Weighted genetic risk scores (GRS) were determined from lung function related risk alleles and used to investigate their interaction with improved air quality. Adjusted linear mixed models were fitted. Results: FEV<sub>1</sub> and FVC were below predicted values at baseline (mean z-scores < 0) but z-scores increased on follow-up. Air pollution levels fell during the study period (e.g. NO<sub>2</sub> from a median of 33.4 to 19.7 µg/m<sup>3</sup>). Reduction of air pollution was associated with an increase of z-scores for FEV<sub>1</sub> and FEV<sub>1</sub>/FVC. For a decrease of 10 µg/m<sup>3</sup> in NO<sub>2</sub>, the z-score for FEV<sub>1</sub> increased by 0.14 (95%CI: [0.01; 0.26]). However, with an increasing number of lung function related risk alleles, the benefit from improved air quality decreased (interaction between improved air quality (NO<sub>2</sub>) and GRS: p=0.029). Conclusions: Reduction of air pollution is associated with a relative improvement of lung function, still on-going in subjects >75 years. However, the beneficial effects of improved air quality also depend on the genetic make-up.

## 004.02I. Social and Environmental Determinants and Health 1

### 004.02.49. Effects of Night-Time Screen-Based Media Device Use on Adolescents' Sleep and Health-Related Quality of Life

Mireille Toledano

*Michael O. Mireku<sup>1</sup>, Mary M. Barker<sup>2</sup>, Julian Mutz<sup>1</sup>, Iroise Dumontheil<sup>3</sup>, Michael S. Thomas<sup>3</sup>, Martin Röösli<sup>4</sup>, Paul Elliott<sup>1</sup>, Mireille B. Toledano<sup>1</sup>*

- 2. Department of Health Sciences, University of York, London, United Kingdom.*
- 3. Department of Psychological Sciences, Birkbeck, University of London, London, United Kingdom.*
- 4. University of Basel, Basel, Switzerland.*

**Abstract:** Background/Aim: Sleep deprivation among adolescents has reached epidemic levels. In this study we investigated the associations between screen-based media device (SBMD) use and sleep and health-related quality of life (HRQoL). Methods: We analysed baseline data from a large cohort of 6,616 adolescents from 39 schools in and around London, United Kingdom, participating in the SCAMP study. Exposure was self-reported SBMD use (including mobile phone, tablet, eBook reader, laptop, television etc.) within one hour before sleep and whether use occurred in the dark or in a room with light on. Outcomes included variables generated from self-reported weekday and weekend bed, sleep and wake times; sleep quality using dimensions from the Swiss Health Survey; and HRQoL estimated using the KIDSCREEN-10 questionnaire. Results: Over two-thirds of adolescents reported using at least one SBMD within the hour before sleep and about a third of adolescents reported using their mobile phone in darkness. Night-time use of mobile phones and televisions was associated with higher odds of late wake time on weekdays (OR = 1.60, 95% CI [1.05, 2.44] and OR = 1.71, 95% CI [1.15, 2.55], respectively). Use of mobile phones, televisions or at least one SBMD was associated with all adverse weekend sleep outcomes. Whereas there was a 31% increase in the odds of insufficient sleep duration for those who used mobile phones in a room with light on, mobile phone use in the dark was associated with a 147% increased odds of insufficient sleep duration compared to no night-time mobile phone use. Likewise, adolescents who used mobile phones in darkness reported poorer HRQoL compared to those who did not use mobile phones. Conclusion: SBMD use within one hour before sleep was associated with adverse sleep outcomes and HRQoL among adolescents. Although adverse effects of night-time use of mobile phones and televisions on sleep outcomes were observed, the effects were stronger when use occurred in darkness.

#### **004.02.50. Correlates of Stress and Depression in Early Pregnancy in a Low-Income Minority Population**

Claudia Toledo-Corral

*Claudia Toledo-Corral<sup>2</sup>, Lu Gao<sup>1</sup>, Thomas Chavez<sup>1</sup>, Brendan Grubbs<sup>3</sup>, Rima Habre<sup>1</sup>, Theresa M. Bastain<sup>1</sup>, Genevieve Dunton<sup>1</sup>, Frank Gilliland<sup>1</sup>, Carrie Breton<sup>1</sup>*

Abstract: Prevalence estimates for depression during pregnancy vary widely with the highest rates in women of lower socioeconomic status and racial/ethnic minorities. Similarly, prenatal stress is also common and can adversely impact both maternal quality of life and fetal development. The aim of this study was to determine socio-demographic and environmental correlates of psychosocial stress and depression in 171 participants of the Maternal And Developmental Risks from Environmental and Social Stressors (MADRES) pregnancy cohort of lower income, predominantly Hispanic women in Los Angeles. The Perceived Stress Scale was used to assess psychosocial stress with a score of 40 indicating the highest level of perceived stress. The Center for Epidemiologic Studies Depression Scale was used to assess depression, with a cut-off score of 16 indicating probable depression. Mutually adjusted linear regression models were employed to evaluate statistically significant predictors of stress and depression. Hispanic ethnicity and years lived in the US were significantly associated with both stress and depression, with recent Hispanic immigrants experiencing the least amount of stress, and immigrants having lived in the US more than 20 years or having been born in the US having less stress compared to non-Hispanic individuals. Despite experiencing the least perceived stress, recent Hispanic immigrants were at most increased risk of being depressed. Being employed, working more than 40 hours a week, having a history of smoking or exposure to second hand smoke, and lack of sleep were all associated with increased perceived stress and depression in early pregnancy. Calenviroscreen 3.0 score, an index of pollutant burden and vulnerability, was not associated with stress or depression. Risk factors for perceived stress and depression in early pregnancy are multifactorial. Teasing out the relative contributions of race, acculturation, and the environment remains a challenge.

#### **004.02.51. The Impact of Socio-Environmental Drivers and Japanese Encephalitis in Shaanxi, China, a Bayesian Spatial Analysis**

Xin Qi

*Xin Qi<sup>2</sup>, Shaobai Zhang<sup>1</sup>, Wenbiao Hu<sup>3</sup>, Guihua Zhuang<sup>2</sup>*

*2. School of Public Health, Xi'an Jiaotong University, Xi'an, Shaanxi, China.*

*3. School of Public Health and Social Work, Queensland University of Technology, Brisbane, QLD, Australia.*

**Abstract:** Background: With the progress of global climate change and more extreme weather events, areas with lower mosquito borne disease incidence also meet with resurgence of disease. This study examined the association of meteorological and socio-demographical factors with Japanese encephalitis JE (2006-2014) in Shaanxi, China. Methods: JE data at the county level in Shaanxi were supplied by Shaanxi Center for Disease Control and Prevention. Population and socioeconomic data were provided by China Population Census in 2010 and statistical yearly book. Meteorological data were acquired from China Meteorological Administration. A Bayesian conditional autoregressive model was used to examine the association of meteorological and socioeconomic factors on JE. Results: A total of 1,197 JE cases were included in this study. The north of Shaanxi had lowest JE incidence while the south had the highest in most of the study years. Urbanization rate was inversely associated with JE incidence in the whole study period. Meteorological variables were more significantly associated with JE incidence between 2012 and 2014 than earlier years. The north had higher incidence from August to October, 2013 than the middle and south, which may be associated with the excessive precipitation in the north in July, 2013 with 1-3 months lag effect. The spatial residual variations indicated that the whole study area had more stable risk (0.80-1.19 across all the counties) between 2012 and 2014 than earlier years. Conclusion: Extreme weather outweighed other variables in association with spatial pattern of JE incidence. Public health interventions need to be implemented to reduce JE incidence, especially in rural areas and after extreme weather, e.g., rainfall.

## **O04.02.52. Exploring Socio-Environmental Determinants of Pediatric Asthma Disparities in South Carolina**

*2. Pediatrics, Medical University of South Carolina, Charleston, SC, United States.*

**Abstract:** Treating childhood asthma symptoms through an emergency department (ED) visit is a major burden for both patients and healthcare systems. One opportunity that could improve understanding of risk and ultimately lead to improved public health strategies to reduce ED visits is a better understanding of socio-environmental determinants of disease. The objective of this research is to explore the spatial distribution of pediatric asthma ED visits across South Carolina in order to better understand geographic patterns of socio-environmental risks and disparities, and to support hypothesis generation for future epidemiologic study. To achieve, we map overall ED visit rates, the white/non-white ED visit rate ratio, and socio-environmental factors including median family income and point pollution sources by ZIP code tabulation area (ZCTA) in South Carolina for the period 2005-2015. Results show that elevated ED visit rates exist in rural areas, that low income areas generally coincide with high rate areas, and that there are relatively large statewide disparities between non-white and white residents. In summary, our results reveal striking disparities in the burden of asthma across South Carolina warranting further study.

**004.02.53. Assessing Associations between School Facility Condition, Neighborhood Environment, and Respiratory Health in Public Schools: An Application of Ultrahigh Dimensional Variable Selection Method on Big Data**

Yi Lu

Yi Lu<sup>1</sup>, Wangjian Zhang<sup>1</sup>, Ziqiang Lin<sup>2</sup>, Shao Lin<sup>1</sup>

1. *Department of Environmental Health Science, University at Albany, SUNY, ALBANY, NY, United States.*

2. *Department of Mathematics and Statistics, University at Albany, SUNY, Albany, NY, United States.*

**Abstract:** Background: While poor school facility conditions were associated with impaired academic performance in large-scale studies, less research has assessed its health impact among students. Furthermore, strong correlations between variables made it difficult to assess a wide range of environmental factors in one model. In this study, we aim to assess the impact of school and home environmental factors on student's respiratory health in a multi-pollutant model by applying an innovative variable selection method. Method: A case-control study was conducted using statewide hospital records from patients aged 4 to 18 during 2010-2013 in upstate New York. Emergency department (ED) visits due to respiratory diseases were defined as cases, while visits due to gastrointestinal diseases, injury, and appendicitis were used as controls. Each patient was assigned to a school based on the information on patient's age, home address, and school zones. A set of 128 variables indicating school facility conditions and school or home neighborhood environmental hazards were included in the variable selection process. Iterative sure independence screening was applied to construct the final multi-pollutant regression model. Result: Eighteen environmental factors were chosen for the final model, including 11 indicators of school facility conditions and 7 indicators of traffic/industrial emission around the school/home. The strongest associations were found between respiratory ED visit and conditions of tile floor, foundation type, noise from air-conditioning or traffic, PM2.5 level in home neighborhood, active leak in classroom, and heating fuel system (increased risks ranged from 9% to 17%). Conclusion: Application of advanced variable selection method allows construction of multi-pollutant models with wide range of environmental factors. Specific school facility conditions potentially play a crucial role in student's respiratory health even after controlling for neighborhood environment.

## **O04.02.54. Preventing Poorer Health and Shorter Lives**

Adetoun Mustapha

*Adetoun Mustapha<sup>1</sup>*

*1. Epidemiology and Biostatistics, MRC-HPA Centre for Environment and Health , Imperial College London, Lagos, Nigeria.*

Abstract: In its 1948 constitution, the World Health Organization (WHO) defined human health in a broader sense as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." Epidemiological evidence has shown that a range of factors such as income, education, social status, social support networks, gender, race, genetics, physical environment, individual behaviours, access to and use of health services, influences health outcomes. An approach that addresses both individual-level and population-level determinants of health is therefore important for disease prevention and health promotion. Results of studies presented in this session reveal disparities in the burden of various health outcomes in different social and environmental settings in similar populations and how the use of technology, such as screen-based media devices, is affecting health. What are the ethical bases to address these disparities at both local and global levels? With rapid urbanization, will increased use of screen-based media devices add to the mental health burden globally? What are the responsibilities of technology companies and stakeholders in addressing the impact of technology-use on well-being and social determinants of health? What are the dilemmas and barriers to creating a society in which everyone has a chance to live a long and healthy life? How can public health practitioners enable policy and actions to address these dilemmas and barriers? Ethical perspectives on the interaction between material disadvantage, its social consequences and other contextual aspects of individual lives that determine health and longevity will be discussed. Ways to facilitate multidimensional approaches to health improvement that involves multiple institutions making simultaneous progress on a variety of fronts to address inequalities within and between countries will be explored.

## S04.02A. Innovation in Community-Based Assessment of Residential Wood Smoke Exposure, Health and Solutions

### **S04.02.01. Using Sensors to Distinguish Indoor and Outdoor Source Mechanisms and the Role of Interventions on Particulate Matter Exposure in Smoke-Impacted Homes**

Abstract: Indoor and outdoor PM<sub>2.5</sub> continuous monitoring was conducted in eight Hobart, Tasmania homes over a four-week period each to evaluate interventions to reduce the impact of ambient woodsmoke emissions on indoor air quality. The homes were between 2.3 and 15 km from a regulatory ambient PM<sub>2.5</sub> monitoring station. Week one provided baseline information, week 2 intervention was all doors and windows closed, week 3 air conditioning was placed on recirculation and week 4 was a portable HEPA air cleaner. Studies were conducted in two waves: wave one in July/August and wave 2 in August/September. Preliminary data indicate that outdoor PM<sub>2.5</sub> varied substantially between homes and the regulatory site. Indoor/outdoor PM<sub>2.5</sub> ratios for each week ranged from 0.09 to 10.3 (median 0.60). The air cleaner intervention led to the lowest indoor concentrations and I/O ratios in only 2 of the 8 study homes. Inspection of the continuous data indicates that lower concentrations during week 4 in these two homes appeared to be more strongly related to a (presumably coincidental) reduction in the frequency or intensity of indoor emission events, rather than any increase in particle removal. Furthermore outdoor concentrations were strongly reduced during wave 2 compared to wave 1 reducing infiltration and the demand for air cleaning. This presentation will consider alternative reasons for the apparent poor performance of the air cleaning interventions.

## **S04.02.02. Systematic Identification and Prioritization of Communities Impacted by Residential Woodsmoke in British Columbia, Canada**

Sarah Henderson

*Kris Y. Hong<sup>1</sup>, Scott Weichenthal<sup>2</sup>, Arvind Saraswat<sup>4</sup>, Gavin H. King<sup>4</sup>, Michael Brauer<sup>3</sup>, Sarah B. Henderson<sup>1</sup>*

- 3. School of Population and Public Health, The University of British Columbia, Vancouver, BC, Canada.*
- 4. British Columbia Ministry of Environment, Surrey, BC, Canada.*

**Abstract:** Background: Residential woodsmoke is an under-regulated source of fine particulate matter (PM<sub>2.5</sub>), often surpassing mobile and industrial emissions in rural communities in North America and elsewhere. In the province of British Columbia (BC), Canada, many municipalities are hesitant to adopt stricter regulations for residential wood burning without empirical evidence that smoke is affecting local air quality. The objective of this study was to develop a retrospective algorithm that uses 1-hour PM<sub>2.5</sub> concentrations and daily temperature data to identify smoky days in order to prioritize communities by smoke impacts. Methods: Levoglucosan measurements from one of the smokiest communities were used to establish the most informative values for three algorithmic parameters: The daily standard deviation of 1-hour PM<sub>2.5</sub> measurements; the daily mean temperature; and the daytime-to-nighttime ratio of PM<sub>2.5</sub> concentrations. Alternate parameterizations were tested in 45 sensitivity analyses, and 23 smaller communities (populations < 80,000) were ranked by the number of smoky days identified within a 2-year period. Results: Using the most informative parameter values on the most recent two years of data for each community, the number of smoky days ranged from 5 to 277 out of 730. Heat maps visualizing seasonal and diurnal variation in PM<sub>2.5</sub> concentrations showed clear differences between the higher- and lower-ranked communities. Some communities were sensitive to one or more of the parameters, but the overall rankings were consistent across the 45 sensitivity analyses. Conclusions: This information will allow stakeholder agencies to work with local governments on implementing appropriate intervention strategies for the most smoke-impacted communities. It was also used to identify communities for more detailed assessment using mobile monitoring.

### **S04.02.03. Mobile Monitoring Capability for Citizen Science Approaches to Smoke Exposure Mapping**

Michael Brauer

*Matthew Wagstaff<sup>2</sup>, Kathleen E. McLean<sup>1</sup>, Arvind Saraswat<sup>3</sup>, Sarah B. Henderson<sup>1</sup>, Michael Brauer<sup>2</sup>*

- 2. School of Population and Public Health, The University of British Columbia, Vancouver, BC, Canada.*
- 3. British Columbia Ministry of Environment, Surrey, BC, Canada.*

**Abstract:** Background: Residential woodsmoke is the dominant source of ambient air pollution in many smaller communities throughout the heating season, which raises concerns about individual and public health. Given the localized nature of this source and the spatial variability in ambient concentrations, more spatially resolved data can help communities to adequately characterize woodsmoke impacts and to implement interventions at the local scale. We made mobile monitoring equipment and online mapping tools available to citizen action groups to collect and visualize their own residential woodsmoke data. Methods: First, we conducted fixed and mobile monitoring in three woodsmoke-impacted communities in British Columbia (BC), Canada to establish the general relationship between levoglucosan within fine particulate matter (PM<sub>2.5</sub>) and Delta-C (880 - 370nm) measurements from a dual wavelength aethalometer. Second, we used this relationship to build an online PM<sub>2.5</sub> mapping tool using the Shiny package for R. Finally, we loaned the aethalometer and its integrated global positioning system (GPS) to citizen scientists in other woodsmoke-impacted communities to assess whether they could feasibly collect and visualize their own data with the assistance of a comprehensive user guide. Results: The relationship between daily levoglucosan PM<sub>2.5</sub> and Delta-C varied across the first three communities, but the slope of the pooled data was 1:1 with an R<sup>2</sup> value of 0.90. Citizen groups were able to collect mobile monitoring data. Following multiple modifications to simplify for lay users, the online Shiny application was successful in providing citizen groups with useful woodsmoke maps. Conclusions: Citizen groups can effectively collect and visualize mobile woodsmoke monitoring data if given adequate support from academic and government partners, especially in the early part of the study period.

#### **S04.02.04. Using Distributed Air Sampling to Distinguish Spatial Contributions of Woodsmoke from Other Particulate Sources in a Medium-Sized City**

Jane Clougherty

*Jane E. Clougherty<sup>1</sup>, Ian Longley<sup>2</sup>, Brett Tunno<sup>3</sup>, Gustavo Olivares<sup>2</sup>, Elizabeth Somervell<sup>2</sup>, Sam Edwards<sup>2</sup>, Guy Coulson<sup>2</sup>*

*1. Environmental and Occupational Health, Drexel University Dornsife School of Public Health, Philadelphia, PA, United States.*

*2. National Institute for Water and Atmospheric Research (NIWA), Auckland, New Zealand.*

*3. Department of Environmental Health, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA, United States.*

Abstract: During winter nights, woodsmoke from home heating may be a substantial source of air pollution in smaller cities and towns. In New Zealand towns with relatively little background air pollution, and substantial reliance on woodburning, we have the unique opportunity to examine spatial variance in woodburning-related pollution, and to disentangle its contribution from that of other sources (i.e., diesel). Few studies to date have been able to isolate spatial patterns in exposures during daytime and nighttime, nor to do so using woodsmoke-specific tracers (e.g., levoglucosan), to separate its contribution from that of other sources (e.g., diesel). We captured seven-day integrated samples of fine particulate matter (PM<sub>2.5</sub>), and elemental and organic tracers of woodsmoke and diesel emissions, during daytime and nighttime hours, across one city, over three weeks in early winter. At a subset of sites, we also sampled during hypothesized "peak" evening woodburning hours, to differentiate emissions during active residential woodburning, vs. overnight smoldering. Concentrations of PM<sub>2.5</sub> were, on average, twice as high during nighttime than daytime. Much greater differences were observed, however, in woodsmoke-related tracers (e.g., levoglucosan, potassium) and indicators of treated- or painted-wood burning (e.g., arsenic, lead). Only nitrogen dioxide (NO<sub>2</sub>), calcium, iron, and manganese (common tracers of vehicular emissions) were higher during daytime. Levoglucosan and most PAHs were higher during "active" woodburning, vs. overnight smoldering. Our time-stratified spatial sampling approach detected substantial variability across the study area, and established a strong contribution of woodsmoke to nighttime PM<sub>2.5</sub>. Daytime vs. nighttime differences were greater than differences observed across sites. Traffic, especially diesel, contributed substantially to daytime NO<sub>2</sub> and localized gradients in non-woodsmoke-related constituents.

#### **S04.02.05. Informing Interventions through Use of a Dense Monitoring Network for Rural Woodsmoke Impacted Communities**

Curtis Noonan

*Curtis Noonan<sup>1</sup>, Ian Longley<sup>2</sup>, Brett Taylor<sup>1</sup>, Gustavo Olivares<sup>2</sup>, Tony Ward<sup>1</sup>*

*1. School of Public and Community Health Sciences, University of Montana, Missoula, MT, United States.*

*2. National Institute of Water and Atmospheric Research, Auckland, New Zealand.*

**Abstract:** Introduction. Rangiora is a rural town in South Island, New Zealand where the use of wood for home heating is prevalent. The West Silver Valley is a historic mining area along the Coeur d'Alene River in northern Idaho, U.S. Due to cold temperature inversions and the predominant use of wood fuels for domestic heating, both communities (and others like them) often exceed health-based standards for particulate matter (PM10 in New Zealand and PM2.5 in the US). Using low-cost PM monitors, we provided policymakers, community members and students across both communities with tools to visualize temporal and spatial variance in ambient woodsmoke. Methods. We deployed 13 low-cost solar powered monitors across Rangiora in 2017 and 12 across the West Silver Valley in 2018, capturing PM2.5 at one-minute intervals over a period of seven and four weeks respectively. Following a quality control procedure, data were ingested into a visualization system previously used by NIWA for presenting weather forecasts and climate summaries for New Zealand. In addition to engaging with residents and state air quality agency personnel, we worked with school administrators to introduce opportunities for students to utilize these dense network air monitoring tools within the context of their science-based curricula. Results. The low-cost monitors exhibited a high degree of stability with nearly 100% data recovery. The data was used to create maps of air quality that described previously unknown spatio-temporal variation in air quality. Animations of the data effectively communicated the highly dynamic nature of air quality and exposure, informing community and regulatory uncertainty over the validity and representativeness of fixed regulatory monitoring sites. Conclusion. A PM sampling network, when combined with visualization tools, reveals new information at a sub-community level that can be used to illustrate fine-grained exposure assessment, stimulate engagement and inform decision making.

## **S04.02.06. Global Evidence of Adverse Health Effects Associated with Residential Wood-Burning**

Jennifer Peel

*Jennifer L. Peel<sup>1</sup>, Maggie L. Clark<sup>1</sup>*

*1. Colorado State University, Fort Collins, CO, United States.*

Abstract: Evidence supporting an association between short-term and long-term exposure to several air pollutants, including fine particulate matter, ozone, nitrogen dioxide, and carbon monoxide matter, and multiple health effects is robust. However, evidence regarding exposure to air pollutants emitted from specific sources is more limited. Residential wood-burning emits various components of air pollution and is an important source of ambient, household, and indoor air pollution in many locations throughout the world. In many lower- and middle-income countries, wood, and more broadly biomass, is used by a large proportion of the population for cooking and heating needs and contributes to both household and ambient air pollution. In high-income countries, residential wood-burning is primarily for heating purposes and varies substantially by region and by economic drivers; however, even in high-income countries residential wood-burning can be an important source for both indoor and ambient air pollution. Globally, there have been efforts to reduce exposures resulting from residential wood-burning through the use of improved technology, alternative fuels, regulations, and other approaches, with varying degrees of success. Here, we will review evidence of adverse health effects associated with residential wood-burning from various fields, including ambient air pollution, household air pollution, indoor air pollution, and controlled human exposure studies; we will draw from related evidence, such as wildfire smoke. Synthesizing evidence from across these fields allows for a broader picture of the current evidence, including areas of inconsistent evidence and research needs.

## POSTER SESSIONS

Sunday, August 26 & Monday, August 27: Student Poster Competition

P01. Weather, Climate and Disasters 1

**P01.0020. The Research on National Heat Vulnerability Assessment of China**

ZongHao Du

*ZongHao Du<sup>1</sup>, Mike Z. He<sup>2</sup>, Jie Ban<sup>1</sup>, Qing Wang<sup>1</sup>, Tiantian Li<sup>1</sup>*

*1. National Institute of Environmental Health Chinese Center for Disease Control and Prevention, Beijing, China.*

*2. Department of Environmental Health Sciences, Columbia University Mailman School of Public Health, New York, NY, United States.*

**Abstract:** Background: At present, many countries and regions have conducted heat vulnerability assessment studies to effectively identify vulnerable areas and populations. In China, heat vulnerability assessments have been conducted in some areas, but there is a lack of coverage across many parts of the country. The impacts of heat vulnerability are still unknown for most areas in China. Objectives: We aim to establish a preliminary heat vulnerability index system in China. Based on the establishment of a nationwide county-scale heat vulnerability index, we assessed the spatial distribution of heat vulnerability in China. Methods: We used principal component analysis to reduce the dimension of heat vulnerability indicators. The heat vulnerability index of each county was calculated by a summation of the principal component scores of the corresponding districts and counties. In order to better intuitively understand the distribution of China's heat vulnerability index, we displayed the results of the index on a spatial map. Results: The average value of the heat vulnerability index is 13.84, with a median of 14, and a standard deviation of 1.77. The high vulnerability areas, defined with a heat vulnerability index value of 16-22, include a total of 394 counties/districts. Low vulnerability areas, defined with a heat vulnerability index value of 5-13, include a total of 1061 counties/districts. The spatial pattern map of the heat vulnerability index indicates that there are many areas with low heat vulnerability in the southeastern coastal areas and central regions, and there are many areas with high heat vulnerability in the northeast and western regions. Conclusion: Geographic, urbanization, economic, and health factors are the primary influencing factors of China's heat vulnerability. Low-income groups, low-education groups, ethnic minorities, and the elderly are particularly vulnerable to the effects of heat in China.

## **P01.0040. Using Ambient Temperature and Internet Search Query to Predict Seasonal Influenza Outbreaks**

Yuzhou Zhang

*Yuzhou Zhang<sup>1</sup>, Hilary Bambrick<sup>1</sup>, Kerrie Mengersen<sup>1</sup>, Shilu Tong<sup>1</sup>, Wenbiao Hu<sup>1</sup>*

*1. QUT, Brisbane, QLD, Australia.*

**Abstract:** The discovery of the dynamics of influenza outbreaks remains a great challenge. The research aims to better predict seasonal influenza outbreaks using climate and big data in Brisbane and Gold Coast, Australia. Weekly influenza notifications, climate data (ie., temperature and rainfall) and big data (ie., internet search query (ISQ)) between January, 2011 and December, 2016 were collected from Queensland Health, Bureau of meteorology, Australia and Google Trends, respectively. A time-series cross correlation function (CCF) was used to compute the correlations between independent variables and influenza over a range of time lags. Increasing duration index ( $\alpha$ ) and increasing intensity index ( $\beta$ ) were used to discover the characteristics of influenza outbreaks. Time series seasonal autoregressive integrated moving average (SARIMA) and regression tree model with climate and ISQ were developed to predict influenza epidemics. The CCF showed that temperature at lag of 1-10 week in both two study settings was inversely associated with influenza, whereas ISQ at lag of 1-7 week was positively associated with the influenza. The largest  $\beta$  value was found in 2015. The inclusion of ISQ and temperature improved the predictive performance of SARIMA model (Brisbane:  $\beta_{ISQ} = 2.42$ ,  $\beta_{temperate} = -25.12$ , increased agreement: 8%; Gold Coast:  $\beta_{ISQ} = 0.38$ ,  $\beta_{temperate} = -7.73$ , increased agreement: 6%;  $p < 0.05$ ). Regression tree model showed that when internet search query  $\geq 65$  and weekly mean maximum temperature  $< 21$ o C, the relative risk (RR) of influenza was 1.6 and 2.9 respectively in Brisbane, whereas internet search query  $\geq 66$  and weekly mean maximum temperature  $< 23$  o C, the RR of influenza was 2.8 and 1.1 separately in Gold Coast. Our results suggested big data in conjunction with temperature can be used to predict influenza outbreaks, which can be considered as a pre-requisite for constructing early warning systems using these data.

## **P01.0050. Assessing the Impact of Cold and Heat Waves on Physical Activity in a Sub-Tropical Urban Population**

Janice Ho

**Abstract:** Background: Extreme temperatures are increasing due to climate change, however research of their impacts on health behaviour are rare. While cold winter temperatures have been identified as a barrier to physical activity, an increase of extremely hot temperatures due to climate change may also potentially affect frequency of physical activity. This study aims to estimate the change of self-reported frequency of outdoor physical activity (PA) during cold and heat waves in a sub-tropical urban population and identify its predictors. Methods: A prospective population-based cohort telephone survey study was conducted in an Asian sub-tropical city, a week after a 2016 coldwave and followed-up 1.5 years after, a week after a 2017 heatwave. Measures on self-reported changes in outdoor PA in heat and cold waves, sociodemographic variables, health status, warning awareness, temperature-related attitudes and knowledge, and protective behaviours were collected. We conducted multivariable logistic regression analyses to assess predictors of change in outdoor PA over the two extreme temperature events. Results: Temperature and other meteorological variables were significantly different during the cold and heat waves from that prior. The response rate at follow-up was 42.8% (435/1017). Overall, more participants (53.3%) reported a decrease in PA in either or both the heat and cold waves, than reported an increase (10.3%), while 36.3% of participants maintained consistent PA in both the cold and heat waves. Decreased PA was associated with females, worsened health status in winter, awareness of temperature, and certain protective behaviours, while increased PA was associated with students, those under 45, higher income, and better health status in summer. Conclusions: Our findings suggest a greater decrease of outdoor PA during cold and heat waves, and identify gender, age, income, health status, temperature-related awareness, and protective behaviours to be associated.

## **P01.0060. Seasonal Variation in Microclimates and the Role of Regional Weather and Environmental Factors**

Abstract: Microclimates are an important component of our ecosystem, and can impact human health through heat-related injuries or by affecting disease vectors. Research on microclimates can be difficult; our understanding of the temporal and environmental variation of microclimates is limited. Microclimate data (temperature and relative humidity) were collected over a twelve-month period in a small community in Ecuador, and summarized for over each 24-hour collection period. Using generalized linear models with generalized estimating equations, we assessed the variability of microclimate variables across time and environmental variables, including urbanicity, elevation and vegetation coverage. With local weather station and remotely-sensed climate data, we assessed the relationship between regional weather and microclimates. Two-hundred and eighty-seven log-days of data were collected; the absolute maximum temperature was in July, and the absolute minimum occurred in August. Relative humidity of 100% occurred frequently during the sampling period; the absolute minimum occurred in March. Some microclimate variables were more temporally stable than others (mean, median, and minimum temperature and maximum relative humidity); urban sites had higher temperature variability ( $p=0.0169$ ) and rural sites had higher mean relative humidity ( $p=0.0137$ ), compared to suburban areas. Microclimate temperature variables were associated with remotely-sensed surface temperature ( $p=0.047$ ). Microclimate minimum ( $p=0.0001$ ) and mean ( $p=0.045$ ) temperature were associated with climate station temperature minimum and mean measures, respectively. Relative humidity mean ( $p<0.0001$ ), median ( $p<0.0001$ ), minimum ( $p=0.038$ ), and maximum ( $p=0.0018$ ) were associated with the number of days with precipitation at the climate station. These data demonstrate the need for climate and health researchers to reconsider the meaning and impact of climate variables across spatial scales.

## **P01.0070. Are Per Capita Carbon Emissions Predictable across Countries?**

Cheng-Kuan (Calvin) Lin

**Abstract:** Background China, and many developing countries in Asia followed similar economic growth patterns, which is well explained by the flying geese (FG) model. The phrase FG paradigm was coined originally by Kaname Akamatsu in 1930s and presented to world academia after World War II. It intended to explain the catching-up process of industrialization in late comer economies. Japan, NIEs and China followed the path and had similar economic growth development trajectories. Our "flying S" hypothesis states that if a country locates in a same FG region and the energy matrix is relatively constant, the per capita CO<sub>2</sub> emission curves will mirror to the leading geese in the same FG group. Method Historical CO<sub>2</sub> emission data was obtained from literature review. By sector CO<sub>2</sub> emission of Taiwan and China were obtained from national reports and calculated from bottom-up method. Sigmoid shaped non-linear mixed effect model was further applied to examine the ex post data with 1000 simulated predictions to construct 95% empirical bands from these fits. By multiplying by estimated population, we predicted total emissions of 6 selected countries in the same FG group. Results Per capita emission of CO<sub>2</sub> from the same FG group does mirror to each other, especially among second and third industrial sectors. We estimated an annual 18648.72 Million tons (Mt) of CO<sub>2</sub> emission (95%CI=9770.40-23618.88) and 9030.48 MtCO<sub>2</sub> (95%CI=2887.92-15677.28) in China and India, respectively, in 2030. Conclusion the study bridges a well-known FG paradigm in macroeconomics to a Climate change study and proposes "flying S" hypothesis to predict and explain GHG emissions of the same FG countries in Asia. By exploiting the empirical data to the theory, we provided an alternative framework to predict CO<sub>2</sub> emission of selected countries in 2030 and beyond.

## **P01.0080. Air Conditioning and Heat-Related Illness in Detroit, Michigan, USA: A Community-Based Participatory Epidemiologic Analysis**

**Abstract:** Intro: Heatwaves are increasing with climate change. Heat-associated health events are borne disproportionately by populations without air conditioning (AC) access--often minority and low-income groups. Detroit, Michigan has well-documented health disparities, including heatwave-associated mortality and hospitalizations. "Heatwaves, Housing, and Health: Increasing Climate Resiliency in Detroit" (HHH), a community-based participatory research (CBPR) collaboration of 5 community-based organizations with a university, investigated the hypothesis that odds of reported heat related illness (HRI) would be greater among respondents with central AC or window unit AC versus no AC and among those with poorer self-rated health. We also piloted a method to increase community partner engagement in the analysis phase of the research. Methods: From 2016-2017, 103 geocoded Detroit residents were surveyed regarding attitudes and behaviors related to heatwaves and HRI occurrence in the past 5 years. Academic partners selected the initial confounders and, after instruction on the use of directed acyclic graphs (DAGs), the collaboration proposed alternate DAGs and confounders. Using logistic regression, HRI was regressed on AC type or health status, and the co-selected confounders, including housing and neighborhood characteristics, utility cost concerns, and age. Alternate models suggested by the DAG were examined. Results: The odds of HRI among those with window AC were 2.86, (95% confidence interval (CI)= 0.69, 11.89) and with no AC 1.39 (95%CI = 0.41, 4.67) compared to those with central AC. The odds of HRI among people with fair/poor health vs. good/excellent health were 2.91 (95% CI=1.25, 6.82). The CBPR co-analysis showed potential confounding by the housing and neighborhood characteristics. Conclusions: In Detroit, HRI may be associated with health status but not AC use. CBPR co-analysis can enhance epidemiologic analyses of community-specific social and health vulnerabilities.

## **P01.0090. Impact of Extreme Heat on End-Stage Renal Disease Patients in the Northeast US Using Selected Clinical Outcomes**

Richard Remigio

*4. School of Public Health, Boston University, Boston, MA, United States.*

**Abstract:** Many studies on extreme heat and health have shown associations with morbidity and mortality within the general population around the world. However, there is a paucity of data regarding how extreme heat event may impact highly vulnerable populations such as individuals living with end-stage renal disease (ESRD) patients. We investigated the associations between exposure to extreme heat events and clinical parameters in urban ESRD patients undergoing hemodialysis (HD) in three northeastern cities. We used physical and clinical measures collected during HD visits between 2001 to 2012 in three cities: Boston, MA; New York City, NY, and Philadelphia, PA. We extracted meteorological data collected at the nearest meteorological stations from National Oceanic and Atmospheric Agency (NOAA). We identified extreme heat events using same-day (lag0) and one-day lag (lag1) 95th percentile threshold of the distribution of the daily maximum temperature or heat index values for each location. We analyzed the association between exposure to extreme heat events inter-dialytic weight gain (IDWG), predialysis systolic and diastolic blood pressure (pre-SBP, pre-DBP), and mortality and hospitalization using linear mixed effect regression adjusting for seasonality, long-term trends, and day of the week. We used time stratified case-crossover study design for the analysis of hospitalization and mortality data. Exposure to extreme heat event (both lag0 and lag1) was associated with significant decreases in mean IDWG, pre-SBP, and pre-DBP in all three cities. We observed increased mortality among patients residing in Boston, but not in New York or Philadelphia. Findings regarding Hospitalization were not statistically significant. Outdoor extreme heat can affect clinical outcomes among hemodialysis patients. These findings could inform heat management guidelines and treatments for ESRD patients in the context of a changing climate.

**P01.0100. Single-Day Inclement Weather Events is an Adherence Barrier for Treatment among Hemodialysis Patients in Urban Northeastern Cities**

Richard Remigio

Abstract: Accessing essential health care services is a challenge during inclement weather disturbances that disproportionately impacts medically fragile populations such as end-stage renal disease (ESRD) patients who receive outpatient dialysis. Epidemiologic evidence regarding this relationship is needed to inform adaptation strategies. The overall goal of this study is to investigate the association between inclement weather conditions such as precipitation, snowfall, snow depth, and wind on missed hemodialysis appointments in selected United States (US) northeastern cities: Boston, MA (BOS); New York City, NY (NYC), and Philadelphia, PA (PHL) from 2010 to 2012. We extracted total daily total precipitation, total snowfall, total snow depth, fastest 2-minute wind speed (WSF2), and fastest 5-second wind speed (WSF5) from national weather databases. The relationship between the occurrence of inclement weather events and missed appointments was investigated using marginal logistic regression to determine population-level effects for each location. Inclement snowfall days exhibited consistent increased odds for missed appointments in BOS (Odds Ratios (OR) 4.63 and 95% confidence interval (CI) 2.30-9.31), NYC (OR=1.66; CI: 1.08-2.55), and PHL (OR=1.70; CI: 1.30-2.22). Inclement rainfall days also exhibited a significant impact on HD patients in PHL (OR 1.81; CI: 1.37-2.40); and during inclement snow depth days in NYC and PHL. BOS and PHL demonstrated significant associations during sustained windy days (WSF2). Our results showed that inclement weather conditions have impact on missed appointments among hemodialysis patients. There is need to maintain uninterrupted critical health care and access to medically fragile communities in local climate resilience strategies. As such, weather forecasting has utility for predicting rates of location-specific missed appointments. Coordination between dialysis centers and health providers can enhance medical care preparedness and delivery.

## **P01.0110. Ambient Temperature and Mortality in Australia: An Evaluation of Risk and Attributable Burden for Different Temperature Exposures**

Jian Cheng

*2. Anhui Medical University, Department of Epidemiology and Health Statistics, School of Public Health, Hefei, Anhui, China.*

**Abstract:** Background: Non-optimum temperatures, including heat, cold and big temperature variability, can affect human health, but the relative contribution of these exposures to mortality and the pattern of population's adaptation have not been fully understood yet. Objectives: This study examined the death risk after exposure to different non-optimum temperatures (i.e., heat, cold, and short-term temperature variability), and associated death burden. Population's adaptation, measured as the pattern of death risk over time, was also analysed. Methods: We modelled associations of mortality with heat during warm season, with cold during cold season, and with temperature variability all year round, separately, in five largest Australian cities (Sydney, Melbourne, Brisbane, Adelaide and Perth), from 2000-2009. Optimum temperatures, above or below which death risk would continuously rise, was used as the reference to calculate the relative risk (RR) of heat and cold, and to estimate the attributable fraction. We used the estimates of temperature variability that have been reported in our previous research. Results: We observed similar death risk for heat (RR: 1.020, 95% confidence interval (CI): 1.013-1.027) and cold (RR: 1.013, 95% CI: 1.005-1.020), and the lowest death risk for temperature variability (RR: 1.005, 95% CI: 1.003-1.007). There was no clear and consistent increasing or decreasing pattern in death risk associated with different exposures in most cities. Among the estimated total attributable deaths, most were due to cold (53.6%), followed by contributions from temperature variability (33.1%) and heat (13.3%). Conclusion: On average, cold and heat in Australia had comparable size of death risk, which was greater than risk of temperature variability, and most temperature-induced deaths were from cold and temperature variability.

## **P01.0120. Comparative Assessment of Heat-and-Cold-Related Emergency Department Visits in China and Australia: Population Vulnerability and Attributable Burden**

Jian Cheng

*Jian Cheng<sup>1</sup>, Yongming Zhang<sup>2</sup>, Wenyi Zhang<sup>3</sup>, Zhiwei Xu<sup>1</sup>, Hilary Bambrick<sup>1</sup>, Shilu Tong<sup>4</sup>, Wenbiao Hu<sup>1</sup>*

*3. Institute of Disease Control and Prevention of PLA, Center for Disease Surveillance of PLA, Beijing, China.*

*4. Shanghai Jiao-Tong University, Shanghai Children's Medical Centre, Shanghai, China.*

**Abstract:** Background: Non-optimal ambient temperatures have detrimental impacts on mortality worldwide, but little is known about the difference in population vulnerability to non-optimal temperatures and temperature-related morbidity burden between developing and developed countries. Objectives: We estimated and compared the associations of emergency department visits (EDV) with non-optimal temperatures in terms of risk trigger temperature, the average slope of exposure-risk function and attributable risk in 12 cities from China and Australia. Methods: We modelled the associations of EDV with heat during warm season and with cold during cold season, separately, using generalized additive model after controlling for temporal variations. Population vulnerability within a given region was quantified with multiple risk trigger points including minimum risk temperature, increasing risk temperature and excessive risk temperature, and average coefficient of exposure-risk function. Fraction of EDV attributable to heat and cold was also calculated. Results: We found large between- and within-country contrasts in the identified multiple risk trigger temperatures, with higher heat and cold trigger points observed in Australia than in China. Heat was associated with a relative risk (RR) of 1.009 [95% confidence interval (CI):1.007, 1.011] in China, which accounted for 5.9% (95% CI: 3.2%, 8.5%) of EDV. Higher RR of heat was observed in Australia (1.014, 95% CI: 1.010, 1.018), responsible for 4.0% (95% CI: 2.3%, 5.7%) of EDV. For cold effects, the RR was similar between two countries, but the attributable fraction was higher in China (9.6%, 95% CI: 6.1%, 12.9%) than in Australia (1.5%, 95% CI: 0.0%, 2.9%). Conclusions: Exposure to heat and cold had adverse but divergent impacts on EDV in China and Australia. Further mitigation policy efforts incorporating region-specific population vulnerability to temperature impacts are necessary in both countries.

**P01.0130. A Time Series Analysis of Associations between Climate Change and Heat Related Illnesses and Development of Heat Health Warning System in Thailand**

Chuleekorn Tanathitikorn

*Chuleekorn Tanathitikorn<sup>1</sup>, Richard McNally<sup>1</sup>, Anil Namdeo<sup>2</sup>, Nikki Rousseau<sup>1</sup>*

*1. Newcastle University, Institute of Health & Society, Faculty of Medical Sciences, Newcastle, United Kingdom.*

*2. Newcastle University, Transport Operations Research Group, School of Engineering, Newcastle, United Kingdom.*

Abstract: A heat health warning system (HHWS) is not set up in Thailand and there is an increasing number of heat - related illnesses (HRI) yearly. As a result of this, the aims of this study is to implementing a suitable threshold level for HHWS in Thailand, which could be different from NOAA guideline. Method: This study were divided into 3 phases with mixed method approach. In phase 1, Daily HRI of hospital admissions from the ICD10 database with diagnosis T67 (Effects of heat and light) were collected between January 2010 to December 2014. Daily temperature and humidity from the same period were obtained. Heat index (HI) was calculated according to the Steadman equation. Time series and Poisson regression analysis were used to find out the relationship between HRI and heat index controlling for day of the week and holiday indicator, for lag times of 1- 7 days. Relative risk (RR) and 95% confidence interval were calculated in each increment of inter-quartile range (IQR) change of HI by each region of Thailand. Next, e-Delphi technique was applied to elicit the opinions of 16 experts involved in climate research. Lastly, to verify the phase 2 findings, a focus group discussion with key stakeholders and policy makers was planned. Results: RR increase 33% (95%CI: 29%-38%) when HI increase per IQR (7.3) in Thailand. The relative risks at 75th percentile of HI at lag 0 of Southern, Northern, Central and Northeast regions were 5.56, 21.76, 79.59, and 39.75, respectively. Threshold level for HHWS are divided to 3 levels, which are pre-alert, higher alert and highest alert level. Based on expert's opinions, the pre- alert level is the level of HI below 75th percentile, the higher level is the level of HI from 75th percentile to 90th percentile. Lastly, the highest level is start from 90th percentile of HI. Conclusion: The level of HI has a positive association with HRI and the suitable warning threshold level for HHWS of Thailand are different from United State of America.

## **P01.0150. The Role of Temperature and Temperature Variability in Risk of Stroke**

Sebastian Rowland

*Sebastian Rowland<sup>1</sup>, Allan Just<sup>2</sup>, Amelia Boehme<sup>3</sup>, Johnathan Rush<sup>2</sup>, Sandy Wong<sup>2</sup>, Brook Frye<sup>2</sup>, Jeff Goldsmith<sup>4</sup>, Itai Kloog<sup>5</sup>, Marianthi-Anna Kioumourtoglou<sup>1</sup>*

- 4. Biostatistics, Columbia University, New York City, NY, United States.*
- 5. Dept. of Geography and Environmental Development, Ben-Gurion University of the Negev, Beersheba, Israel.*

**Abstract:** Background: While it has been well established that extreme temperatures are a risk factor for adverse health, including acute cardiovascular events, previous epidemiologic research has failed to flexibly assess diurnal variation in temperature and, thus, comprehensively understand the impact of temperature dynamics. We investigated the association between multiple metrics of temperature exposure and stroke hospitalizations. Methods: We used stroke hospitalization and residential address data from the Statewide Planning and Research Cooperative System (SPARCS) dataset of the New York Department of Health for 2012 and 2014 over New York State. We linked events to hourly temperature and relative humidity from the North American Land Data Assimilation System (NLDAS). We employed a time-stratified case-crossover design, also matched on hour of event, to examine whether different temperature metrics over the 48-hr prior to event are related to risk of stroke. The metrics included max and mean, standard deviation (SD), max absolute first difference, and SD of first differences. Results: We observed 48,497 events over the study period. Higher mean and max temperature were associated with 4.9% (95%CI: 0.7, 9.0%) and 9.0% (95%CI: 3.8, 15.0%) increase in the rate of stroke admissions per 10oC, respectively. Different variability metrics showed different strengths of association. We found 0.7% (95%CI: -0.1, 1.8%) increase in risk per 1oC increase in SD, 1.7% (95%CI: 1.3, 2.2%) per 0.1oC increase in SD of first differences, and 1.9% (95%CI: 1.3, 2.5%) per 0.5oC increase in max absolute first differences. Conclusion: Our findings suggest that temperature changes may increase risk of stroke. The observed associations depended on the metric used, implicating different biological or behavioral mechanisms. More research is needed to understand the relevant biological mechanisms and appropriate interventions.

**P01.0160. Effect Modification of Heat Wave Characteristics and Influence on Variability in Mortality in Northwestern India**

**Abstract:** While the relationship between heat waves and health has been studied, questions remain regarding health effects of heat waves that occur in climates with high baseline temperatures, especially under a changing climate. Additionally, questions remain regarding causal inference, and whether prior results for high effects early in season apply universally. Few studies have assessed the relationship between heat waves and health outcomes in India and no study assessed how heat wave characteristics, including intensity, duration and seasonality, influence the health burden associated with heat. Data from city registrars and local meteorological departments were collected (period 2000-2012, varying by community) for 4 communities in Northwestern India. Propensity Score Matching (PSM) was used to obtain attributable mortality and relative risk of mortality in regards to a variety of heat wave definitions (n=13) incorporating heat waves' duration, intensity as well as timing in season. Relative risk of heat waves (risk of mortality comparing a heat wave day to matched a non-heat wave day) ranged from 1.28 [95% CI: 1.11, 1.46] in Churu to 1.03 [95% CI: 0.87, 1.23] in Idar and Himmatnagar. Some heat wave definitions resulted in a high relative risk of deleterious health effects, however so few days match those criteria that the absolute health burden was small. Heat waves that occurred later in season were much more deleterious to health, contributing to more attributable deaths than early season heat waves. Heat waves have harmful health effects even in places with high baseline temperatures, and the effect of heat waves varied by heat wave definition as well as by health endpoint. Unlike previous studies, heat waves occurring later in season were more harmful across the study area. These findings are critical from a policy perspective, as a tool for policy makers to determine the most important local criteria for declaring a heat wave.

## **P01.0170. Putting the Economic Cart before the Healthy Horse: Barriers and Opportunities for Health Co-Benefits in Climate Change Mitigation Policies**

Annabelle Workman

Abstract: Numerous health benefits can result from the implementation of climate change mitigation policies. At a time when ambitious action is urgently needed, accounting for benefits of climate change action in policy development is imperative. The domestic and near-term benefits to human health that arise from implementing climate mitigation policies can provide a strong justification for developing increasingly ambitious climate change policies. The policy development process is complex, especially for a multi-scale, multi-sectoral policy issue such as climate change. To gain a better understanding of the process, and how health fits, we interviewed Australian and European Commission (EC) climate change policy-makers. We developed case studies for Australia and the European Union (EU) using theoretical insights from the political economy literature in conjunction with data from the interviews and analysis of key Australian Government and EC documents. We found that the complexities of the policy-making process, in conjunction with politico-economic and institutional realities, can create barriers for the integration of health co-benefits into climate change mitigation policies[1]. In better understanding the policy development processes for these Parties to the United Nations Framework Convention on Climate Change (UNFCCC), we identify specific strategies to enhance the role of health co-benefits in the development of Australian and EU climate change mitigation policies, which may be relevant more broadly, at the sub-national level and for other Parties to the UNFCCC. Insights gained from our research can be used by environmental health researchers to support the translation of research into policy-making. [1] Workman, A., G. Blashki, D. Karoly, and J. Wiseman. 2016. "The Role of Health Co-Benefits in the Development of Australian Climate Change Mitigation Policies." *International Journal of Environmental Research and Public Health* 13 (9). doi:10.3390/ijerph13090927.

## **P01.0180. Proposition of Lags and Variables for a Cold-Health Watch and Warning System in the Province of Quebec**

Bixun Yan

*2. Institut National de Santé Publique du Québec (INSPQ), Quebec City, QC, Canada.*

Abstract: Extreme cold and hot weather events have serious impacts on human life and health, and have been shown to increase daily mortality. The heat waves of recent years led many countries to establish their heat-health watch and warning systems (HHWWS) to prevent the effects of extreme heat. In spite of known impacts, there have not been many studies that concern warning systems for cold. In temperate regions, winter mortality is generally higher than the rest of the year. This is especially true for the province of Quebec, where the winter is long and usually very cold. Thus, it is of interest to establish a cold-health watch and warning system. However, cold studies are a bit different than heat studies. On the one hand, the delay between exposure to high ambient temperatures and mortality is short, whereas the effects for extremely cold temperatures is usually much longer (for example, 21 days in studies of associations between meteorological variables and cold-health outcomes). A watch and warning system concerns rather a high excess mortality caused directly by meteorological variables such as the daily minimum and maximum temperatures. However, since the direct effects of these meteorological variables decrease with time, it will be impossible to take a very long lag for a watch and warning system. On the other hand, a HHWWS usually takes into account temperature and humidity, but in order to establish a cold-health watch and warning system, we have to consider different meteorological variables. Therefore, the objectives of this study are to: 1) determine the lag for the cold-health watch and warning system (based on an approach from HHWWS), and 2) propose relevant meteorological variables for this system. To evaluate the performances of this system, it is applied to the province of Quebec. It is a good start to establish a general and elaborate cold-health watch and warning system in this province.

## **P01.0190. Impact of Anomalous Temperature on Injury Mortality by Age and Sex in the USA**

**Abstract:** Background Extreme temperatures which deviate from long-term averages will be more frequent as the global climate changes, and could have adverse health consequences. Much previous work has focussed on how mortality from natural causes is affected by daily or multi-day hot/cold episodes, and not on weather patterns that reflect inter-annual variations, as expected under global climate change, nor on injuries. Methods We formulated a Bayesian spatiotemporal model to estimate how deviations from long-term averages of mean monthly temperature as well as number of monthly extremes affect injury mortality in the contiguous USA. Our model incorporates how mortality varies by age, sex, state of residence, and month and year. Importantly, it associates monthly injury death rate to inter-annual variation of temperature from the average 30-year climate. We calculated injury death rates for each age group, sex, state and year from national vital statistics over a 34-year period (1980 to 2013) and monthly population-weighted temperature statistics from the ERA-Interim project, which combines predictions of a physical model with ground-based and satellite measurements. Results Risk of dying from unintentional injuries increased in anomalously-warm June/July months in males, up to 1.8% (95% CI 1.2 - 2.5) per degree Celsius in July. Males  $\leq 55$  years were also at increased risk throughout spring and summer months, by up to 2.0% (1.0 - 3.2) in May. Only females 5-24 years were at increased risk in anomalously-warm months, and only in summer months. Intentional injuries showed no consistent relationship with anomalous temperatures. We will also show findings on transport accidents, accidental falls, accidental drowning, self-harm and assault. Conclusion More frequent or extreme anomalously-warm months will increase mortality for unintentional injuries in spring and summer months for males. There will be no change in mortality from intentional injuries.

## **P01.0210. Pollen Counts in Four Canadian Cities: Geographical Variation between 2008 and 2012**

Cecilia Sierra-Heredia

Abstract: Pollen grains from anemophilous plants represent an important class of aeroallergens in ambient air. High concentrations of aeroallergens, including tree and grass pollen are associated with increased asthma-related emergency department visits and hospitalizations across Canada. The geographical distribution of species of plants is dependent on multiple factors, including precipitation, soil composition and moisture and average high and low temperatures. Five "floristic zones" that support the growth of different aeroallergen-producing plants have been defined across Canada. Here we examine the differences among four Canadian cities (Vancouver, Edmonton, Winnipeg and Toronto) situated in four of the Canadian floristic zones. We describe pollen counts with respect to: start and end dates of the pollen seasons; season length; and annual pollen counts between 2008 and 2012. These cities and years were chosen to cover the antenatal and perinatal windows of sensitization for the participants in the Canadian Healthy Infant Longitudinal Development (CHILD) birth cohort. Pollen season was defined considering the dates when the 5% and 95% of the annual total was recorded for each pollen. The following table presents the 5-year average for pollen count and season duration for trees and grasses. With these data and estimates of traffic-related-air-pollution exposure we will present the combined effects in the development of early-life asthma. Trees Grasses City Average pollen (grains/m<sup>3</sup>) Average season duration (days)

Average pollen	Average season duration	Participants
Vancouver/42926.2/92.6/1497.8/74.6/992		
Edmonton/7368.4/71.2/1522.3/54.4/774		
Winnipeg/16904.1/50.8/1564.3/70.6/738		
Toronto/16915.5/71.2/991.8/107/770		

The geographical differences may suggest the particular needs of atopy prone and sensitized individuals in each city, and the potential need to account for local contexts when designing public health initiatives related to aeroallergen information and to green space.

## **P01.0220. Spatio-Temporal Analysis of Dengue Cases in Queensland, Australia, 2010-2015**

Rokeya Akter

*Rokeya Akter<sup>1</sup>, Suchithra Naish<sup>1</sup>, Michelle Gatton<sup>1</sup>, Hilary Bambrick<sup>1</sup>, Wenbiao Hu<sup>1</sup>, Shilu Tong<sup>1</sup>*

Abstract: Dengue, an acute infectious disease, is a public health concern in northern Queensland, Australia characterised by annual outbreaks. This study explored spatio-temporal characteristics of dengue cases in Queensland, to identify high-risk areas at fine spatial scale and thereby help in planning resource allocation for dengue control measures. Notifications of dengue cases for Queensland at statistical local area (SLA) level were obtained from Queensland Health for the period 2010 to 2015. Spatio-temporal analysis was performed, including plotting of seasonal distribution and decomposition of cases, using linear regression models and creating choropleth maps of cumulative incidence. The space-time scan statistic (SaT Scan) and a geographical information system were used to identify and visualise the space-time clusters of dengue cases. A total of 1773 dengue cases with 632 (35.65%) autochthonous cases and 1141 (64.35%) overseas cases were reported in Queensland during the study period. Both autochthonous and overseas cases occurred more frequently in autumn and showed a geographically expanding trend over the study period. The most likely cluster of autochthonous cases (RR=54.52,  $p<0.001$ ) contained 50 SLAs in the north-east region of the state around Cairns occurred during 2013-2015. A cluster of overseas cases (RR of 60.81,  $p<0.001$ ) occurred in Herston (Brisbane) during 2012 to 2013. These results could be useful in directing future investigations on risk factors and effective interventions in these high-risk areas.

**P01.0230. Kidney Injury within Arid/Semi-Arid Climates: A View Nationally and Within the San Luis Valley, Colorado**

Amber Vaughn

*Amber Vaughn<sup>1</sup>, Katherine A. James<sup>1</sup>*

*1. Colorado School of Public Health, Aurora, CO, United States.*

**Abstract:** Background: Chronic kidney disease (CKD) is a non-communicable disease considered a global health problem. CKD of unknown or non-traditional causes (CKDu) subtype is localized to geographical areas with causes poorly understood. CKDu prevalence is common among rural, agricultural, working-aged men in dry climates. We examine prevalence of CKD with exposure of arid climates nationally, and kidney injury with dehydration and agricultural occupations within the San Luis Valley (SLV), Colorado. Methods: State level data (N=51) of prevalence of CKD (2014), stratified by age, were used for simple linear regression between CKD and arid states. In the second tier of analysis utilizing the SLV cohort (N=1890) and excluding people with diabetes. Logistic regression was used comparing kidney injury with dehydration and agricultural occupations adjusting for age, sex, ethnicity, blood pressure, and smoking. Results: Arid states (n=16) have a 0.07 increased prevalence of CKD compared to non-arid states for populations 20-64 years in 2014 (95%CI:0.03-0.10, p-value:<0.01). Within the SLV (n=1142), people with kidney injury were 1.78 times more likely to drink low amounts of water compared to people drinking high amounts of water after adjusting for risk factors (95%CI:1.27-251, p-value:<0.01). Outdoor labor jobs were looked at as a factor for kidney injury. Conclusions: Kidney injury is prevalent within the SLV, and exposure to dehydration is a risk factor. Additionally, state aridity could help locate areas of increased risk for CKDu. This further understanding helps identify sensitive populations and provides support for local interventions.

**P01.0240. Development and Selection of an Appropriate Model of City Level Dengue Fever Incidence in China Using Autocorrelation, Population, Weather, Climate, Vegetation, and Land Use Predictors**

Megan Clegg

*Megan A. Clegg<sup>1</sup>, Gail Williams<sup>1</sup>, Wenyi Zhang<sup>2</sup>, Samuel Hundessa<sup>1</sup>, Yuming Guo<sup>3</sup>*

**Abstract:** Background/Aim: Dengue Fever is a vector borne disease that predominantly effects countries in tropical latitudes. In recent years the incidence rate in many countries has been increasing identifying the need for accurate predictive models. We develop and assess several models of dengue fever incidence at the 'City' administrative level in China using autocorrelation, population, weather, climate, vegetation, and land use variables. Methods: The dataset was first cleaned and processed to weekly time scales. Initial descriptive analysis included incidence rates, correlation, spatial and temporal autocorrelation analysis. Several models were then built and assessed for their suitability. These included the Zero-Inflated Negative Binomial Model, the Distributed Lag Non-Linear Model, the Generalised Additive Model with random effects, and the Random Forest Model. Results: Models were successfully fitted for all four methods. While many studies identified through a literature review used some form of Negative Binomial or Poisson model, this method was not suitable for this data because of both the variation in cases across different City categories, and the nonlinear nature of the relationship between cases and weather variables. The Distributed Lag Nonlinear Model also did not yield satisfactory results, with the model substantially overpredicting almost all case counts. The Generalised Additive Model fit the observed data very well, however, it was reliant on the random effects specified for 'City' to produce such a good fit and could not be used for predictions as a result. Finally, a Random Forest Model was investigated. This model was successful in fitting the observed cases without using the City as a covariate, it allowed non-linear effects to be considered, and achieved consistent results across numerous random seeds. Conclusion: The Random Forest algorithm is a suitable method to model case counts of Dengue Fever in China.

## P01. Built Environment, Noise and Greenness 1

### **P01.0250. The Association between Spatial Pattern of Green Space with High Vitality and Hyperthermia Mortality on the Extreme High Temperature**

Ejin Kim

*2. Center for Social and Environmental Systems Research, National Institute for Environmental Studies, Ibaraki, Japan.*

*3. Interdisciplinary Program in Landscape Architecture, Seoul National University, Seoul, Seoul, Korea (the Republic of).*

**Abstract:** Background/Aim We investigated the influence of spatial pattern of green space with high vitality, on hyperthermia mortality in South Korea, between 2004 and 2013. Methods We used remotely sensed data and geographic information to determine the amount of district vegetation. The landscape indices have been developed to evaluate the spatial patterns of green space with high vitality such as configuration and composition of patches. We analysed using a case crossover design for estimating the association between spatial pattern of green space with high vitality and hyperthermia mortality on the extreme high temperature by the quartiles of districts greenness [classified using the Normalized Difference Vegetation Index (NDVI)]. In our study, after investigating the vulnerable groups of the extreme high temperature, we examined the association between spatial pattern of green space with high vitality and hyperthermia mortality on the extreme high temperature, among the vulnerable groups. Results Our data showed that the relative risk of hyperthermia mortality at the high level of each index was lower than reference level, low level of each index, the number of patch and patch density (NP, PS). Also this pattern was significant statistically for those who were lower education level group and outdoor work occupations. Conclusions In this study, it showed that green spaces were reduced probability hyperthermia mortality, and spatial patterns as well as the amount of simple green spaces played an important role. The overall green area is wide, and one large patch is effective in lowering hyperthermia mortality.

## **P01.0260. Exploring the Utilitarian and Non-Utilitarian Bicycling Behaviors of North American Women Cyclists**

Huyen Le

*Huyen Le<sup>1</sup>, Fionnuala Quinn<sup>2</sup>, Alyson West<sup>3</sup>, Steve Hankey<sup>1</sup>*

*2. Bureau of Good Roads, Fairfax, VA, United States.*

*3. University of North Carolina, Chapel Hill, NC, United States.*

**Abstract:** Background: Increasing bicycling is a common goal to increase physical activity. Studies have shown that women bike at a lower rate than men due to various factors; few studies have examined attitudes and perceptions of women cyclists at a large scale. This study aims to fill this gap by examining the bicycling behaviors of women cyclists across North America. Methods: We analyzed an online survey of 1,868 women cyclists in the US and Canada. The survey recorded respondents' bicycling skills, attitude, perceptions of safety, surrounding environment, and other factors that may affect the decision to bicycle for transport and recreation. We used chi-squared and non-parametric tests to examine the differences among groups of cyclists. We then utilized tree-based machine learning methods (e.g., bagging, random forest, boosting) to select the most common motivations and concerns of these cyclists. Results: We found that perception of safety (e.g., traffic, motorist behavior, lighting) were significantly different among women cyclists across age groups, bicycling skill, and education levels. Tree-based model results indicate that perceptions of safety, wayfinding, bicycle facilities, hills, and concerns about health were among the most important factors for women to bike for transport or recreation. The average classification error rates were around 9-12%. Cross validation performed on 20% of the sample resulted in moderate error rates (9-25%). Conclusions: Our study suggests opportunities for designing healthy cities for women. Cities may enhance safety to increase bicycling rates of women through investing in bicycle facilities and lighting infrastructure as well as enforcing speed limits and aggressive behavior from motorists. Our study also outlines how promotional and education materials designed for women in the non-bicycling group may help to change behavior. Future studies to compare bicycling behaviors of cyclists and non-cyclists of both genders would be useful.

**P01.0280. Impact of the Built Environment on Active Travel: A Longitudinal Study of 12 U.S. Metropolitan Areas**

Huyen Le

*Huyen Le<sup>1</sup>, Ralph Buehler<sup>1</sup>, Steve Hankey<sup>1</sup>*

*1. Urban Affairs and Planning, Virginia Tech, Blacksburg, VA, United States.*

**Abstract:** Background: Increasing walking and bicycling rates is a common goal for cities to improve community health through physical activity and reduced emissions. Previous studies employed bicycle and pedestrian traffic count data to model spatial patterns of active travel; however, temporal trends have rarely been included in these studies since longitudinal traffic counts do not exist in most jurisdictions. We aim to address this limitation by examining the temporal trends and spatial patterns of active travel in 12 US metropolitan areas (MSA) across 12 years. Methods: We processed pedestrian and bicycle traffic count data from 2004 to 2016 (n=4,773 count locations; 12,832 observations) in the 12 MSAs. At each count location, we tabulated transportation, land use, and socio-demographic variables at three buffer sizes (300m, 500m, and 750m). We used two-level mixed-effect models to examine the multi-year trend and spatial patterns in bicycling and walking during morning and afternoon peak periods. Results: Our models suggest that active travel increased at a rate of 1-6% (bicycle) and 2-3% (pedestrian) per year. Built environment features were significant across models. Close proximity to university campuses, green space, water, and high density employment areas had a positive impact on active travel. The presence of bicycle facilities (e.g., bicycle lanes; off-street trails) were positively associated with higher levels of bicycle traffic. Inclusion of interaction terms suggests that locations with an off-street bicycle facility had a higher rate of increase in bicycle traffic over time. Conclusions: Our study provides evidence for the role of the built environment and transportation network in promoting active travel to increase physical activity and reduce emissions. Health researchers and practitioners could use our model results to quantify health impacts associated with how changes in the built environment and infrastructure influence rates of active travel.

## **P01.0290. Quantifying Residential Access and Exposure to Greenspace Using High-Resolution Remotely Sensed Data: A Case Study of Metro Vancouver, British Columbia**

Ingrid Jarvis

*Ingrid Jarvis<sup>1</sup>, Dave Williams<sup>2</sup>, Lorien Nesbitt<sup>3</sup>, Sarah Gergel<sup>1</sup>, Matilda van den Bosch<sup>3</sup>*

- 1. Forest and Conservation Sciences, University of British Columbia, Vancouver, BC, Canada.*
- 2. Integrated Remote Sensing Studio, University of British Columbia, Vancouver, BC, Canada.*
- 3. School of Population and Public Health, University of British Columbia, Vancouver, BC, Canada.*

**Abstract:** Despite growing evidence demonstrating the health benefits of greenspaces, the potential differences in effect depending on type of greenspace exposure remain relatively unexplored. The present research aims to develop a methodology to (1) identify greenspace using remotely sensed data and (2) model residential access and exposure to greenspace and the relative difference in vegetation type. **Methods:** 2014 RapidEye satellite imagery and LiDAR datasets from 2008-2015 were combined in eCognition for object-based segmentation, and then classified using Random Forest in R to produce a high-resolution (5m) land cover map of Metro Vancouver, Canada. The land cover map includes 14 classes - covering, for example, coniferous, deciduous, shrub, and grass-herb vegetation. Using the land cover map, greenspace access was calculated as the presence of a public park, recreation area or reserve ( $\geq 1$  hectare) within 300m of residential postal codes and greenspace exposure was calculated as the proportion of greenspace and each land cover type, within several buffer zones of residential postal codes. **Results:** The land cover map has an overall accuracy of 89% with a kappa of 0.88. Compared to traditional greenness metrics, such as NDVI, the land cover map provides a more detailed model of the variety and distribution of greenspace. Initial analyses suggest that more urbanized areas have greater access to public greenspace and higher exposure to built-up classes and broadleaf vegetation, with grass-herb vegetation increasingly dominant in rural and agricultural areas. **Conclusions:** This research presents a method of identifying and quantifying greenspace that can be applied widely. Differentiating greenspace access and exposure metrics, including relative distribution of land cover type, will help define which aspects and qualities of greenspaces may provide the most benefits. Such information will provide important guidance for prioritization in urban planning and public health policy.

## **P01.0291. Impacts of Multi-Modal Commuting on Personal Air and Noise Exposures and Airway Inflammation**

Yisi Liu

*Yisi Liu<sup>1</sup>, Bowen Lan<sup>1</sup>, Jeff Shirai<sup>1</sup>, Elena Austin<sup>1</sup>, Changhong Yang<sup>2</sup>, Edmund Seto<sup>1</sup>*

*1. Department of Environmental and Occupational Health Science, University of Washington, Seattle, WA, United States.*

*2. Sichuan CDC, Chengdu, Sichuan, China.*

**Abstract:** Background: Modern mobility can include mixtures of transportation options, which potentially impact pollution exposures and health. Objectives: To investigate variations in traffic-related air and noise pollution exposures and cardiorespiratory effects in different microenvironments in Chengdu, China. Methods: Three sections of a city were chosen as locations for a scripted exposure study: the urban core, a developing neighborhood, and a suburb. Exposures for four commuting modes (car, bus, subway, and shared bike) with overlapping routes were measured using portable instruments (measuring PM<sub>2.5</sub>, Black Carbon, and noise) in summer and winter (5 repeats in each season). We assessed the feasibility of collecting health measures (ECG, breathing rate, respiratory minute ventilation, fractional exhaled nitric oxide, and spirometry measurements) in winter for four healthy, non-smoking young adults. Health measures on commute days were compared to a control measurement collected two days after the last commute. Results: Air pollutant measures showed large seasonal variance, with winter medians more than three times higher than those in summer (PM<sub>2.5</sub>: 33 vs 123 ug/m<sup>3</sup>, BC: 2395 vs 9125 ng/m<sup>3</sup>). The highest PM<sub>2.5</sub> and BC levels were measured in the urban core (both  $p < 0.0001$ ). Noise tended to be higher in the summer, and was higher in the suburb than other neighborhoods ( $p < 0.0001$ ). In summer, riding the subway had the highest pollution levels, while riding a car was found to be the least polluted mode ( $p < 0.0001$ ). In winter, the highest air pollution levels were found for shared bike use ( $p < 0.0001$ ); subway and bus trips had the lowest PM<sub>2.5</sub> and BC level respectively ( $p < 0.0001$ ). Preliminary linear mixed modeling suggested that riding a car may be associated with increased airway inflammation ( $p = 0.004$ ). Conclusion: Results from this study suggest that mode, location and season of transportation impact personal traffic-related pollution exposure and airway inflammation.

**P01.0292. Assessing Associations between School Facility Condition, Neighborhood Environment, and Respiratory Health in Public Schools: An Application of Ultrahigh Dimensional Variable Selection Method on Big Data**

Yi Lu

Yi Lu<sup>1</sup>, Wangjian Zhang<sup>1</sup>, Ziqiang Lin<sup>2</sup>, Shao Lin<sup>1</sup>

1. *Department of Environmental Health Science, University at Albany, SUNY, ALBANY, NY, United States.*

2. *Department of Mathematics and Statistics, University at Albany, SUNY, Albany, NY, United States.*

**Abstract:** Background: While poor school facility conditions were associated with impaired academic performance in large-scale studies, less research has assessed its health impact among students. Furthermore, strong correlations between variables made it difficult to assess a wide range of environmental factors in one model. In this study, we aim to assess the impact of school and home environmental factors on student's respiratory health in a multi-pollutant model by applying an innovative variable selection method. Method: A case-control study was conducted using statewide hospital records from patients aged 4 to 18 during 2010-2013 in upstate New York. Emergency department (ED) visits due to respiratory diseases were defined as cases, while visits due to gastrointestinal diseases, injury, and appendicitis were used as controls. Each patient was assigned to a school based on the information on patient's age, home address, and school zones. A set of 128 variables indicating school facility conditions and school or home neighborhood environmental hazards were included in the variable selection process. Iterative sure independence screening was applied to construct the final multi-pollutant regression model. Result: Eighteen environmental factors were chosen for the final model, including 11 indicators of school facility conditions and 7 indicators of traffic/industrial emission around the school/home. The strongest associations were found between respiratory ED visit and conditions of tile floor, foundation type, noise from air-conditioning or traffic, PM2.5 level in home neighborhood, active leak in classroom, and heating fuel system (increased risks ranged from 9% to 17%). Conclusion: Application of advanced variable selection method allows construction of multi-pollutant models with wide range of environmental factors. Specific school facility conditions potentially play a crucial role in student's respiratory health even after controlling for neighborhood environment.

## **P01.0300. Noise Sensitivity and Annoyance in the HERMES Cohort of Swiss Adolescents**

Louise Tangermann

*Louise T. Tangermann<sup>1</sup>, Apolline Saucy<sup>1</sup>, Danielle M. Vienneau<sup>1</sup>, Beat Schäffer<sup>2</sup>, Jean Marc Wunderli<sup>2</sup>, Nino Küenzli<sup>1</sup>, Martin Rössli<sup>1</sup>*

*1. Swiss Tropical and Public Health Institute & University of Basel, Basel, Switzerland.*

*2. EMPA, Dübendorf, Switzerland.*

**Abstract:** The World Health Organization considers children at particular risk of suffering negative consequences from noise exposure. Knowledge on noise needs to be generated to prevent future harm. This study examines noise sensitivity and annoyance in the HERMES cohort of 892 adolescents in Switzerland. Noise annoyance and sensitivity were measured through questionnaires in adolescents aged 10 to 17, with a follow-up one year later. Participants rated annoyance to five noise sources: road traffic, railway, aircraft, industry, and neighbourhood noise, resulting in a binary score: no (none, little) and yes (clearly, severely). Sensitivity to noise was measured with the Zimmer/Ellermeyer scale, scores ranging from 0 to 27. Scores >14 indicated increased noise sensitivity. The proportions of noise sensitive and noise annoyed participants were calculated. Generalized estimating equations were used to investigate gender and age differences, adjusted for repeated measurements and overall time trend. The exposures to the noise sources were not considered in this analysis. At baseline, 846 students filled out the questionnaire, with 805 participating in the follow-up (participation rate: 95.2%). 24.1% of participants were noise sensitive. The proportions of participants annoyed by the noise sources were: 3.6% (road traffic), 2.0% (railway), 2.7% (aircraft), 1.9% (industry), and 6.7% (neighbourhood). No age and gender differences were observed, except for more males being annoyed by industry noise ( $p=0.019$ ) and more females being annoyed by neighbourhood noise ( $p=0.022$ ). Our study found a quarter of surveyed adolescents being noise sensitive, while the prevalence of annoyance by specific noises was relatively low. This analysis only considered psychometric data: noise experience and the relating personal trait. Future analyses will explore the relationship between these and the actual noise exposure, as well as other health outcomes such as behaviour, cognitive function and symptoms.

## **P01.0310. Long-Term Exposure to Wind Turbine Noise and Incidence of Myocardial Infarction: The Danish Nurse Cohort**

Jeanette Jørgensen

*Elvira Vaclavik Brauner<sup>2</sup>, Jeanette T. Jørgensen<sup>1</sup>, Anne Katrine Dunn-Henriksen<sup>1</sup>, Claus Backalarz<sup>3</sup>, Mette Kildevæld Simonsen<sup>4</sup>, Zorana J. Andersen<sup>1</sup>*

- 1. Public Health, University of Copenhagen, Copenhagen, Denmark.*

- 3. DELTA Acoustics, Hørsholm, Denmark.*
- 4. Diakonissestiftelsen and Parker Institute, Frederiksberg Hospital, Frederiksberg, Denmark.*

**Abstract:** Introduction: Growing evidence supports the idea that traffic noise (road, rail and air) leads to long-term health complications other than annoyance, including myocardial infarction (MI), and similar effects may be expected from wind turbine noise. We examined the association between long-term exposure to wind turbine noise and incidence of MI. Methods: We used the Danish Nurse Cohort with 28,731 female nurses (>44 years) recruited in 1993 or 1999 from entire Denmark, and obtained data on incidence of MI from the National Patient and Causes of Death Registries until 2013. The noise from all wind turbines within a 6000 meters radius within nurses residence between 1982 and 2014 was estimated by Nord2000 method, as the annual mean of a weighted 24-hour average (Lden) at the most exposed façade. We used time-varying Cox regression to link the baseline year mean, 11-, 5- and 1-year moving averages of noise levels to MI incidence. Results: Of 23,994 nurses in the analyses 727 developed MI until 2013. There were 5,601 wind turbines in operation in Denmark between 1982 and 2013, and number of nurses exposed ( $\geq 1$  wind mill within 6000m radius from home) to wind turbine noise was 10% at the cohort baseline in 1993 or 1999, and increased to almost 25% in 2013. Compared to non-exposed nurses at the cohort baseline, we found positive associations with annual mean residential level of wind turbine noise and MI incidence, with hazard ratio (95% confidence intervals) for noise <21.5 dB: 1.29 (0.81-2.03); 21.5-25.4 dB: 1.79 (1.21-2.62); 25.4-29.9 dB: 1.12 (0.70-1.79), and > 29.9 dB: 1.02 (0.62-1.67). Similar pattern and weaker associations were observed with 11-, 5-, and 1-year moving averages, with strongest associations in second quartile of exposure. Conclusion: We found a suggestive evidence of an association between wind turbine noise and MI, but relatively small number of exposed subjects and MI cases, and lack of dose-response relationship demand more studies.

## **P01.0311. Associations of Surrounding Green, Air Pollution and Traffic Noise with General and Mental Health**

Jochem Klompmaker

*Jochem Klompmaker<sup>1</sup>, Gerard Hoek<sup>2</sup>, Lizan Bloemsmas<sup>1</sup>, Ulrike Gehring<sup>2</sup>, Alet Wijga<sup>1</sup>, Bert Brunekreef<sup>2</sup>, Erik Lebret<sup>1</sup>, Nicole A. Janssen<sup>1</sup>*

*1. National Institute for Public Health and the Environment, Bilthoven, Netherlands.*

*2. Utrecht University, Utrecht, Netherlands.*

**Abstract:** Background: Several studies showed indications that mental health is affected by environmental exposures. Objectives: To evaluate the effects of combined exposure to surrounding green, air pollution and traffic noise with general health and aspects of mental health. Methods: We linked a Dutch national health survey of 387,195 adults with an external database on prescription of anxiolytics (N05B), hypnotics and sedatives (N05C) and antidepressants (N06A). Moreover, we added data on surrounding green based on the Normalized Difference Vegetation Index (NDVI) or a land-use database (TOP10NL), annual average air pollutant concentrations (including particulate matter (PM<sub>10</sub>, PM<sub>2.5</sub>), and nitrogen dioxide (NO<sub>2</sub>) and road- and rail-traffic noise to the survey. We used logistic regression models to analyze associations of surrounding green, air pollution and noise exposure with self-reported general and mental health and medication prescription. Results: In single exposure models, exposure to air pollution was positively associated with all outcomes, while surrounding green was inversely associated with all outcomes. For example, for prescription of anxiolytics, we found an odds ratio [OR] of 0.83 (95% CI: 0.79, 0.88) per interquartile range [IQR] increase in green (TOP10NL) in a 1000m buffer and an OR of 1.14 (95% CI: 1.14, 1.19) per IQR increase in NO<sub>2</sub>. Road-traffic noise was only associated with prescription of anxiolytics (OR: 1.05 per 5 dB, 95% CI: 1.02, 1.07). Two-exposure analyses showed that the associations with surrounding green and air pollution generally remained, but they were attenuated. Conclusions: Surrounding green and air pollution were associated with general health and aspects of mental health.

**P01.0312. The Association between Long-term Neighborhood Greenness and Lethal Prostate Cancer in a Prospective Cohort Study of Male Health Professionals in the United States**

Hari Iyer

**Abstract:** Background Emerging literature documents health benefits of natural environments. We studied the association between neighborhood greenness and 26-year incidence of lethal prostate cancer (CaP), effect modification by address type (home or workplace), and mediation by vigorous physical activity. Methods Participants in the Health Professionals Follow-up Study, a nationwide prospective cohort, were followed from 1986 to 2012. We excluded those with history of CaP or missing address. Lethal CaP was defined by metastasis or CaP death. Neighborhood greenness was measured using normalized difference vegetation index (NDVI) with 1km<sup>2</sup> resolution. Participants were assigned NDVI corresponding to their address at start of follow-up, taking averages over four seasonal measures. NDVI was modeled using quintiles. Data were analyzed using sequentially adjusted Cox regression models: 1) age, calendar year, race, family history, smoking, BMI at 21, PSA screening, census median income and home value, walkability index; 2) vigorous and non-vigorous physical activity, current BMI. Results 46,494 participants met eligibility criteria. Men in greener neighborhoods at baseline experienced lower rates of lethal CaP (model 1: Q2 v Q1, aHR: 0.84, 95% CI: 0.67-1.05; Q3 aHR: 0.86, 95% CI: 0.69-1.07; Q4 aHR: 0.77, 95% CI: 0.61-0.97; Q5 aHR: 0.86, 95% CI: 0.69-1.09, ptrend=0.11). Protective associations were strongest among men (39%) reporting work addresses (Q2 v Q1, aHR: 0.73, 95% CI: 0.51-1.02; Q3 aHR: 0.61, 95% CI: 0.42-0.89; Q4 aHR: 0.55, 95% CI: 0.37-0.83; Q5 aHR: 0.65, 95% CI: 0.42-1.00, ptrend=0.0005). Further adjustment for mediators (model 2) did not change effect estimates. Conclusions Our findings suggest a protective association between neighborhood greenness and lethal CaP independent of physical activity, though overall results were not statistically significant. Stronger associations at work suggest benefits may arise from passive rather than active engagement with nature.

**P01.0313. Associations between Traffic-Related Air Pollution and Cardiovascular Disease Risk Factors Were Stronger in More Walkable Neighborhoods: The Cardiovascular Health in Ambulatory Care Research Team (CANHEART) Cohort**

**Abstract:** Introduction Studies suggest living in a more walkable neighborhood may protect against cardiovascular disease risk factors such as hypertension (HTN) and diabetes mellitus (DM) by encouraging physical activity. Walkable neighborhoods, however, often carry higher levels of traffic-related air pollution. Little is known regarding whether synergistic effects may exist between walkability and air pollution on these risk factors. Hypothesis We hypothesized that the association between traffic-related air pollution, hypertension, and diabetes mellitus would be stronger in more walkable areas. Methods We drew a cross-sectional sample of individuals ages 40-74 on January 1, 2008 from the CANHEART cohort. HTN and DM were ascertained using validated algorithms. Walkability (quintiles, Q5 highest, Q1 lowest) was measured using a validated index which has previously been shown to be inversely associated with obesity and diabetes. Exposure to nitrogen dioxide, a valid marker for traffic-related air pollution, was assessed using a land use regression models. The associations were tested using logistic regression with cluster-robust standard errors, adjusting for age, sex, area-level income, ethnicity, and comorbidities. Results 2,618,584 individuals were included in the analysis. Walkability was inversely associated with odds for HTN (Q5 vs. Q1 OR = 0.80, 95% CI: 0.79, 0.82) and DM (Q5 vs. Q1 OR = 0.89, 95% CI: 0.87, 0.91), while NO<sub>2</sub> was positively associated with each (HTN: OR = 1.02 per 10 ppb (1.01, 1.03); DM: OR = 1.11 per 10 ppb (1.09, 1.13)). We observed significant interactions between walkability and NO<sub>2</sub> on odds for HTN and DM, with stronger NO<sub>2</sub> associations in the most walkable neighborhoods. Conclusions We observed significant interactions between traffic-related air pollution and walkability on odds for HTN and DM. This finding suggests that benefits from living in more walkable neighborhoods may be partially offset by stronger negative associations with air pollution.

## **P01.0314. The Relationship between Long-term Exposure to Neighbourhood Greenness and Air Pollution and Cardiovascular Mortality in Urban Areas in Belgium**

**Abstract:** Background Few large-scale studies have evaluated the association between residential green, air pollution and cause-specific mortality. Our study investigates the relationship between long-term residential exposure to green spaces, air pollution and cardiovascular (CV) mortality in adults living in the five largest cities in Belgium. Methods We used the Belgian 2001 census linked to mortality follow-up data (2001-2011) among 18 to 65-year-old adults for the 5 largest cities in Belgium. The data contain individual information on CV mortality (ICD-10 codes I10-I70), sociodemographic variables (age, sex, education level, employment status and housing status), residential history (based on the link with the 1991 census) and annual means ( $\mu\text{g}/\text{m}^3$ ) of air pollution (PM10, PM2.5, NO2 and BC) for the residential addresses. Different measures of green (percentage (+ 600m buffer), proximity and fragmentation of green) based on land use data (CORINE land cover) were available at the scale of census tracts. Cox proportional hazards models, where age was used as the underlying time scale, were performed to probe into CV mortality. Results We studied  $\approx 2$  million adults with 10.25 years of follow-up and observed  $\approx 11,200$  CV deaths. Consistent statistically significant effects were found for the different measures of green in the adjusted models. Hazard ratio's for the % of neighbourhood green per increase in IQR and % of green within a 600m buffer were 0.969 (99% CI 0.952-0.987) and 0.866 (99% CI 0.830-0.905), respectively. Results show independent effects for the measures of green on CV mortality when adjusted for the different pollutants separately. Sensitivity analyses including only non-movers showed similar results. Conclusion Our results suggest a beneficial association between exposure to residential green and CV mortality. Further analyses will be conducted within this study to confirm our results.

## **P01.0315. Modelled and Perceived Noise Exposure and Psychotropic Medication Use**

Enembe Okokon

*Enembe O. Okokon<sup>1</sup>*

*1. Department of Health Security, National Institute for Health and Welfare, Finland, Kuopio, Finland.*

**Abstract:** Background Road-traffic noise can induce stress which may eventually lead to mental health disorders. Mental health problems of noise have not are scant in research. People perceive noise differently, this may affect the extent to which noise contributes to poor mental health at individual level. This paper aimed to assess relationships between perceived or modelled noise and use of psychotropic medication. **Methods** We conducted a survey to evaluate perceived exposures of residents of the Helsinki Capital Region of Finland to road-traffic noise and the associations of these exposures with sleep disorder, anxiety and depression. Respondents were randomly sampled from the Finnish Population registry and data was collected using a self-administered questionnaire. Associations between subjective (annoyance) or modelled façade-noise levels and mental health outcome indicators were assessed using generalised additive models while controlling for socioeconomic, lifestyle and exposure-related factors. **Results** A total of 7321 respondents returned completed questionnaires. The proportion of respondents with self-rated moderate to severe road-traffic noise exposure showed a linear trend with higher categories of modelled noise. About 15%, 7% and 7% of respondents used sedative, anxiolytic and antidepressant medicaments, respectively, in the year prior to the study. Perceived noise exposure was clearly associated with anxiolytic drug use only, OR=1.41 (95% CI: 1.02 – 1.95). There was suggestive association between modelled noise and anxiolytic or antidepressant use. In respondents without a quiet façade, modelled noise was more definitively associated with antidepressant use. Noise sensitivity did not modify the effect of noise but was independently associated with increased use of all medication. **Conclusion** We observed few associations between noise and psychotropic medication use. Noise sensitivity was found to predict psychotropic medication use independently of noise.

**P01.0316. Long-Term Residential Exposure to Environmental Noise and Cardiovascular Disease Onset: A Population-Based Cohort Study**

Larisa Yankoty

*Larisa I. Yankoty<sup>1</sup>*

*1. École de santé publique, Université de Montreal, LAVAL, QC, Canada.*

**Abstract:** Introduction: Cardiovascular effects of environmental noise are a growing concern. However, the evidence remains largely limited to the association between road traffic noise and hypertension and ischemic diseases especially myocardial infarction (MI). Objective: To examine associations between long-term residential exposure to total environmental noise and the onset of cardiovascular MI and strokes in adults of the Island of Montreal. Methods: An open cohort of 1,087,806 adults aged  $\geq 45$  years, free of MI and strokes before entering the cohort was created for the years 2000 to 2014 with the Quebec Integrated Chronic Disease Surveillance System, a systematic surveillance system from the second most populous province in Canada starting in 1996. The exposure to total environmental noise (L<sub>Aeq24h</sub>) at cohort entry was estimated with a Land Use Regression (LUR) model. Onsets of MI and strokes were based on one hospital admission. Cox models were used to estimate associations. Results: We found positive associations between L<sub>Aeq24h</sub> estimated and the occurrence of MI and strokes; hazard ratios adjusted for age, sex, year of entry, social and material deprivation indexes and traffic-related air pollutant (nitrogen dioxide) were respectively 1.10 (95% CI: 1.07-1.13) and 1.06 (95% CI: 1.03-1.09) per 10 dBA. Conclusion: These results suggest that total environmental noise is associated with the onset of MI and strokes. Future work should clarify if associations vary by noise sources, and if pre-existing diseases (e.g. hypertension) mediate such effects.

## **P01.0317. Long-Term Transportation Noise Exposure and Incidence of Ischemic Heart Disease and Stroke**

Andrei Pyko

**Abstract:** Background Exposure to transportation noise is widespread and has been suggested as a risk factor for cardiovascular disease. However, the evidence from longitudinal studies on ischemic heart disease (IHD) and stroke is limited. This cohort study aimed to estimate the association between exposure to noise from road traffic, railways or aircraft and incidence of IHD and stroke. **Methods** We assessed individual long-term exposure to road traffic, railway and aircraft noise based on residential histories in a cohort of 20,012 individuals. The National Patient and Cause-of-Death Registers were used to define IHD and stroke events. Extensive information on potential confounders was available from questionnaires and registers. We computed Hazard Ratios (HR) using Cox proportional hazards regression to assess associations between noise exposure and IHD. **Results** The study base of 245,000 person-years generated 1,363 and 902 incident events of IHD and stroke, respectively. We observed a particularly high risk of IHD in those exposed to all three transportation noise sources at  $\geq 45$  dB Lden, with a HR of 1.57(95%CI 1.06–2.32), and a similar tendency for stroke (HR 1.42; 95%CI 0.87–2.32). While no associations were observed between noise exposure from any of the sources and incidence of IHD or stroke, there were associations between road traffic and aircraft noise exposure 1-5 years prior to the event and IHD incidence in women, with HR of 1.11(95%CI 1.00–1.22) and 1.25 (95%CI 1.09–1.44) per 10 dB Lden, respectively. On the other hand, a decreased risk of IHD was seen for men in relation to road traffic noise exposure (HR 0.86; 95%CI 0.79–0.94 per 10 dB). **Conclusion** No overall associations were observed between noise exposure from different transportation noise sources and incidence of IHD or stroke. However, there appeared to be an increased risk of IHD in women exposed to road traffic or aircraft noise as well as in those exposed to multiple sources of transportation noise.

## **P01.0318. Modeled and Perceived RF-EMF, Noise, Air Pollution and Symptoms in a Population Cohort: Is Perception Key in Predicting Symptoms?**

Marije Reedijk

*4. Netherlands Institute for Health Services Research, Utrecht, Netherlands.*

**Abstract:** Introduction Psychosocial research has shown that perceived exposure can influence symptom reporting, regardless of actual exposure. The impact of this phenomenon on the interpretation of results from epidemiological research of environmental determinants on self-reported health is unclear. Methods In this study we compared associations between modeled exposures, the perceived degree of being exposed to these exposures and reported symptoms (non-specific symptoms, sleep disturbances, respiratory symptoms) for three environmental exposures (radiofrequency electromagnetic fields (RF-EMF), noise, and air pollution) which vary in the degree to which they can be sensorially observed. Participant characteristics, perceived exposures, and self-reported health were assessed with baseline (n=14829, 2011/2012) and follow-up (n=7905, 2015) questionnaires in the Dutch population-based Occupational and Environmental Health Cohort study (AMIGO). Environmental exposures were estimated at the home address using spatial models. Cross-sectional and longitudinal regression models were used to examine the associations between modeled and perceived exposures, and reported symptoms. Results The extent to which exposure sources could be observed likely influenced correlations between modeled and perceived exposure as correlations were moderate for air pollution (rSp=0.34) and noise (rSp=0.40), but less so for RF-EMF (rSp=0.11). Perceived exposures were consistently associated with increased symptom reporting (non-specific, sleep, respiratory). In general, modeled exposures were associated with increased symptom reporting, but these associations were strongly attenuated when perceived exposure was accounted for in the analyses. Discussion Perceived exposure has an important role in symptom reporting. Evaluations of environmental determinants of symptom reporting may result in biased estimates if exposure perception is not taken into account.

## **P01.0319. Human Responses to Biophilic Indoor Environment**

Jie Yin

*Jie Yin<sup>1</sup>, Nastaran Arfaei<sup>1</sup>, Shihao Zhu<sup>1</sup>, Piers MacNaughton<sup>1</sup>, Joseph G. Allen<sup>1</sup>, John Spengler<sup>1</sup>*

*1. Environmental Health, Harvard University, Arlington, MA, United States.*

**Abstract:** Biophilic design, which incorporates natural elements into the built environment, has received increasing attention in both design and health fields. Epidemiological and experimental studies have provided sufficient evidence that contact with outdoor nature has positive impacts on human health and wellbeing. However, the potential for similar health benefits in indoor biophilic environments remains unclear. We designed a randomized crossover study to examine the physiological and cognitive responses to biophilic indoor environments by using virtual reality (VR) and wearable bio-monitoring sensors. In this study, 28 participants spent time in an indoor environment featuring biophilic design elements and one without, with the order of the visit randomized. In each visit, they experienced the same environment for 5-minutes in reality and virtually by using VR. The indoor biophilic environment was associated with a decrease in participants's blood pressure. The overall differential effects for participants experiencing an indoor environment with biophilic elements versus none was 8.56 (95%CI: 5.60-11.52) mmHg lower systolic and 3.57 (95%CI: 0.36-6.78) mmHg lower diastolic blood pressure. In addition, their skin conductance decreased by 0.18 (95%CI: -0.004-0.36)  $\mu$ S and short-term memory improved by 14% (95%CI: 5.3%-23.2%). Moreover, our findings indicate that participants had similar physiological and cognitive benefits in the virtual environment and actual environment. The results indicate that biophilic environment may be beneficial in reduce stress in indoor settings. Additionally, the parity in results in virtual and real environments provides evidence that using VR can be an effective tool to simulate visual exposures when access to the real environment is not feasible.

## P01. Exposure Measurement, Modeling and Other Methodological Issues 1

### P01.0320. Development of Sensor Metadata Library for Exposomic Studies

Ramkiran Gouripeddi

*Nicole Burnett<sup>1</sup>, Ramkiran Gouripeddi<sup>1</sup>, Julio Facelli<sup>1</sup>, Peter Mo<sup>1</sup>, Randy Madsen<sup>1</sup>, Ryan Butcher<sup>1</sup>, Katherine Sward<sup>1</sup>*

Abstract: Exposomic research may utilize multiple sensors to measure individuals' environment and their physiological responses. These sensors measure physical, chemical and biological properties and have wide variations in their capabilities and performance. It is therefore important to provide sensor characterization information in order to make appropriate decisions when selecting and utilizing sensors for research studies and analysis or when performing meta-studies aggregating data from multiple sensors. In this presentation, we discuss the development, organization, and use of a sensor metadata library (SML) developed by the Utah PRISMS Informatics Ecosystem (UPIE) (Grant NIH NIBIB U54EB021973). We performed a needs assessment and utilized the sensor common metadata specifications (SCMS) developed by UPIE in designing the SML. SCMS contains sensor metadata pertaining to the physical device, their deployment and resulting measurement outputs. The SML includes domains describing the physical characteristics of devices, including hardware and software versioning, measurement and/or sample collection characteristics, validation protocols, ownership and additional technical documentation. We implemented the SML using the NeO4j graph database. The SML includes tools for capturing and discovering metadata for new and updated versions of sensors. Sensor owners can submit metadata to the SML using a REDCap survey form, which is then curated and stored. Researchers can visualize stored sensor metadata graphically as interlinked nodes of information. This SML serves as a researcher-facing tool - as a repository of sensor information for researchers to design their exposomic studies and understand their limitations; and an inventory of available sensors for prospective study deployments. It also serves as a source of metadata store for the UPIE for performing semantically consistent metadata driven integration of heterogeneous sensor data streams for exposomic study analysis.

## **P01.0330. Advancing Study Metadata Models to Support an Exposomic Informatics Infrastructure**

Victoria Tiase

*Victoria Tiase<sup>1</sup>, Ramkiran Gouripeddi<sup>1</sup>, Katherine Sward<sup>1</sup>, Nicole Burnett<sup>1</sup>, Ryan Butcher<sup>1</sup>, Peter Mo<sup>1</sup>, Mollie Cummins<sup>1</sup>*

*1. University of Utah, New York, NY, United States.*

**Abstract:** Exposomic research is an emerging field of study that seeks to address environmental exposures and its effects on life, health, and disease development. Research using exposomic data includes those related to the research and development of sensor devices, chemistry of environmental species and exposure pathways. Concurrently, with the increase in biomedical research interests and advances in exposome data collection, data are increasingly available.<sup>1</sup> In order to support such translational exposomic studies, there is a need for an informatics infrastructure along with tools to facilitate access and use by investigators. However, to date, there is no standard or systematic way to model a translational exposomic research study. To support research using personalized and environmental sensor devices, we developed a model for exposomic studies to cover the design, conduct and analytic phases of a study. We reviewed existing study metadata representations and compared them with a sample of publicly available exposome studies from the literature and others elicited from researchers. Gaps were found in how sensor data are represented in the existing study metadata models and in general, a lack of detail into data requirements for exposome studies; all needed for an informatics infrastructure. To address these gaps we consolidated data elements from existing domain specific models. In particular, we incorporated the Sensor Common Metadata Specification (SCMS) into the model. The SCMS is currently being implemented in the Utah PRISMS Informatics Ecosystem (UPIE) and includes metadata of measured data from sensors, the deployment of sensors, and the sensors itself.<sup>2</sup> This model is currently being validated within UPIE for reproducible representations of exposomic studies, and computable specification of study data integration, to support the study of effects of the environment on health and advance the science in this area.

## **P01.0340. Metal Concentrations in Electronic Cigarette Aerosols: Effects of Device Type and Vaping Patterns**

Di Zhao

*Di Zhao<sup>1</sup>, Ana Navas-Acien<sup>2</sup>, Vesna Ilievski<sup>2</sup>, Vesna Slakovich<sup>2</sup>, Angela Aherrera<sup>3</sup>, Bernat Adria-Mora<sup>2</sup>, Pablo Olmedo<sup>2</sup>, Ana Rule<sup>3</sup>, Markus Hilpert<sup>2</sup>*

- 3. Department of Environmental Health and Engineering, Johns Hopkins University, New York, NY, United States.*

Abstract: Electronic cigarettes (E-cigarettes) generate an aerosol that contains metals. Little is known about the effects of device type and vaping patterns on metal exposure. The objectives of this study were (1) to quantify concentrations of 14 metals in aerosol generated by four types of e-cigarettes including two mods (Istick 25 and SMOK) and two pods/cigalikes (BLU and JUUL) and (2) to examine the effects of device type, device power, flavor (tobacco, menthol, fruit, and others), nicotine content, and coil aging on metal emissions. The mods were operated at three power settings. Two new and two used coils were used to examine the effects of coil variability and aging with pale whale flavored e-liquid. In total, 160 aerosol samples were obtained and analyzed. Median metal concentrations ( $\mu\text{g}/\text{kg}$ ) in aerosol generated by each of the two mods were: 3.02 and 20.8 for Cr, 134 and 542 for Cu, 118 and 153 for Fe, 19.6 and 64.0 for Mn, 862 and 2,252 for Ni, 123 and 541 for Pb, 318 and 20.9 for Sn, 3,432 and 3,114 for Zn. Median metal concentrations ( $\mu\text{g}/\text{kg}$ ) in pods/cigalikes were markedly lower than in mods: 0.39 and 0.41 for Cr, 31.0 and 6.02 for Cu, 0.08 and 0.08 for Fe, 0.80 and 0.39 for Mn, 1.32 and 11.9 for Ni, 6.88 and 0.88 for Pb, 0.80 and 0.01 for Sn, 1,247 and 683 for Zn. Metal concentrations depended on power, flavor, nicotine content, and coil age. Device type and vaping patterns had great impact on the levels of harmful metals in the aerosol. Aerosolized metal exposure from e-cigarettes can potentially be reduced though not eliminated if strict e-cigarette manufacturing standards are established.

## **P01.0350. Aggregate Exposure Estimation of Di(2-Ethylhexyl)phthalate in Multiple Cosmetic Products**

Miyoung Lim

*Miyoung Lim<sup>1</sup>, Ji Young Park<sup>2</sup>, Jae-Eun Lim<sup>3</sup>, Hyo-Bang Moon<sup>3</sup>, Kiyoung Lee<sup>1</sup>*

*2. Institute of Health and Environment, Seoul National University, Seoul, Korea (the Republic of).*

*3. Department of Marine Sciences and Convergent Technology, Hanyang University, Ansan, Korea (the Republic of).*

Abstract: In order to estimate the realistic exposure of a chemical, aggregate exposure from multiple consumer products should be considered. Typical aggregate exposure assessment was a form of the simply combined amount of exposure by product. Accurate aggregate exposure assessment should be based on individual's exposure factors and actual chemical contents in products. The aims of this study were to estimate aggregate exposure of Di(2-ethylhexyl)phthalate (DEHP) in multiple cosmetic products by Korean population group and determine the contribution of each product. We collected the exposure factors of 12 cosmetic types (four skincare, three hair care, three body care, and two cleansing products). Field survey staff visited homes and collected product use information using face-to-face interview. In total, 1,001 subjects over 19 years old completed the questionnaire from June to August 2017. The number of subjects was determined by proportionate quota sampling based on the population composition ratio in sex and age distribution. DEHP concentrations for 111 products from the 12 product categories were analyzed by GC-MS/MS. The exposure factor survey showed that 96.4% of the 1,001 subjects used at least one cosmetic product. The detection frequency of DEHP in the cosmetic products was 61.3% and maximum concentrations were 18.6 µg/g at 34 skincare, 24.0 µg/g at 15 hair care, 122.9 µg/g at 23 body care and 75.2 µg/g at 39 cleansing products. The average aggregate DEHP exposure based on individual's exposure factors was  $2.97 \pm 4.00$  µg/kg-bw/day in Korea population. The 30's women group was the group of the highest aggregate DEHP exposure with  $5.21 \pm 6.17$  µg/kg-bw/day which was 6.86 times higher than 60's men group. DEHP exposure contribution by products was in order of body cream, facial cleanser and facial cream. These aggregate exposure data would be useful input data for risk assessment and regulation of DEHP in cosmetic products.

## **P01.0360. An Extended Random-Effects Framework for Meta-Analysis in Environmental Research**

Antonio Gasparrini

*Francesco Sera<sup>1</sup>, Ana M. Vicedo-Cabrera<sup>1</sup>, Ben Armstrong<sup>1</sup>, Antonio Gasparrini<sup>1</sup>*

*1. Department of Public Health, Environments and Society, London School of Hygiene and Tropical Medicine, London, United Kingdom.*

**Abstract:** Background and aim: Two-stage designs have become standard tools in environmental epidemiology. These methods rely on the application of a random-effects meta-analysis to pool results from different locations. However, standard models do not account for potential correlation structures within and between locations, arising for example when pooling multi-parameter associations, multiple levels or hierarchies, and/or longitudinally and spatially-correlated estimates. In this contribution, we illustrate a unified framework and software for meta-analysis that flexibly extends the two-stage design to cover these and other applications. Methods: We extended the standard meta-analytic models along the lines of linear mixed-effects models, by allowing correlation between effect sizes to be modelled through a flexible random-effects structure. We derived (restricted) maximum likelihood estimators, and efficient computational strategies based on profiled methods alternating iterative generalized least squares and Newton-Raphson procedures. The analytic framework and inferential procedures are implemented in a new version of the R package *mvmeta*. Results: The modelling framework and its software implementation will be illustrated in a series of examples, using multi-city time series data for the analysis of health effects of air pollution and temperature. Various case studies will demonstrate different applications, such as: multilevel meta-analysis of effects across locations nested within countries; meta-analysis for spatially-correlated outcomes; longitudinal meta-analysis for repeatedly-measured effects to assess effect modification by time-varying predictors, such as air conditioning. Conclusions: The definition of a unified framework for meta-analysis, along with a freely-available software, will provide researchers with a flexible tool for addressing non-standard pooling problems in two-stage designs applied to environmental studies

Abstract: Since the first clinical diagnosis in 1979, the prevalence of feline hyperthyroidism in the United States has increased from 1 in 300 to 1 in 10 domesticated geriatric cats. Similar prevalence statistics are reported worldwide. Although histologically similar to human toxic nodular goiter, the underlying causes of feline hyperthyroidism remain unknown. There is some evidence that exposure to endocrine-disrupting compounds with thyroid targets may contribute to the development of feline hyperthyroidism and toxic nodular goiter. This includes exposures to brominated flame retardants (FRs), such as polybrominated diphenyl ethers (PBDEs). FR exposure routes (e.g. inhalation) are the same between cats and humans, such that cats can be used as sentinels for human exposures. In this study, silicone passive sampling devices, or cat tags, quantitatively assessed the bioavailable fraction of household FRs. Participating cats wore a cat tag for 7 days, and targeted analysis by gas chromatography mass spectrometry included 41 legacy and current FRs. Preliminary data indicated that 3 non-hyperthyroid cat tags detected a total of 11 PBDEs and organophosphate ethers. Tris(2-chloroisopropyl)phosphate (TCPP), triphenyl phosphate, and BDE-47 were detected above the limit of quantitation in all 3 cat tags. TCPP was detected at the highest concentration in each tag, ranging from 1.35 to 32.3 ng/g cat tag. This study provides proof-of-concept data for the use of silicone cat tags with companion animals and demonstrates that cat tags can compare FR concentrations in homes of hyperthyroid and non-hyperthyroid cats.

## **P01.0380. Quantified Micro-Level Activity Data for Children Aged 1 - 12 Years Old Playing on Turf and Playgrounds**

Nicolas Lopez-Galvez

*Nicolas I. Lopez-Galvez<sup>1</sup>, Robert Canales<sup>1</sup>, Patty Wong<sup>2</sup>, Asa Bradman<sup>3</sup>, James Leckie<sup>4</sup>, Paloma Beamer<sup>1</sup>*

Abstract: The use of synthetic turf in sport fields, parks, yards, and playgrounds in many communities is gaining popularity as a substitute to natural grass. However, there is growing concern regarding the exposure to toxicants released from recycled tire rubber, which is commonly used as an infill material in synthetic turf and playground mats. To better estimate the aggregate exposure and risk to recycled tire rubber used in synthetic turf and playground floors, there is a need to collect detailed information on mouthing activity and dermal contact behaviors. Thus, micro-level activity time series (MLATS) of children aged 1-12 years was analyzed to quantify these behaviors while children played on turf-like locations such as parks, yards, and playgrounds. MLATS data was extracted from a pre-existing dataset of 56 children playing outdoors. Hand and mouth contact frequency, hourly duration, and median contact duration with different objects were calculated for children playing on turf (n = 56), and for children playing on playground structures (n = 24). For children playing on turf, age was negatively correlated with mouthing activity for non-dietary objects. There were significant differences between younger (1-5 years old) and older children (6-12 years old) groups for the mouthing median duration with hands, non-dietary objects and all objects. Males had significantly higher hourly contact duration of both hands with non-dietary objects than females. For children playing on playground structures, although there were no significant differences between genders, there were significant differences between younger (1-5 years old) and older children (6-12 years old) groups for the mouthing frequency with non-dietary objects and all objects, and for mouthing median duration with non-dietary objects. In conclusion, age and contact duration should be considered in performing risk assessment models for mouthing activities when children are playing on artificial turf surfaces.

## **P01.0400. Evaluating Use of Digital PCR in Quantitative Analysis of Microbial DNA in the Indoor Environment**

Samuel Cochran

*2. College of Public Health, The Ohio State University, Columbus, OH, United States.*

*3. Environmental Science Graduate Program, The Ohio State University, Columbus, OH, United States.*

Abstract: Previous methods of detecting and identifying bacteria and fungi in the built environment were reliant on culture-based methods. These methods cannot accurately quantify all microbes present in environmental samples and lead to underestimation of microbial exposures indoors, where we spend 90% of our time. The advent of quantitative polymerase chain reaction (qPCR) and digital PCR (dPCR) has substantially enhanced our ability to quantitatively measure microbial species so to better understand our exposure. While qPCR offers a larger dynamic range, dPCR, the newer technology, promises better repeatability and reproducibility with greater precision at low target copy numbers. For both technologies however, we need to better characterize the accuracy, precision, and reproducibility in use with indoor environmental samples. Another goal for this study is to determine extraction efficiencies in stages during sample analysis. Dust samples-spiked separately with *Escherichia coli*, *Bacillus atrophaeus*, and *Aspergillus fumigatus*-were collected from different carpet types. It was found that 96.57%, 92.88%, and 92.51% of total spiked *E. coli*, *B. atrophaeus*, and *A. fumigatus* DNA, were respectively recovered from low-pile carpet. From medium pile carpet, 84.42%, 81.37%, and 60.96% of total spiked DNA from each respective organism were recovered. The combined efficiencies, accounting for both 'carpet extraction' and DNA extraction, for *E. coli*, *B. atrophaeus*, and *A. fumigatus* (low pile, medium pile) were: 31.00%, 27.10%; 71.80%, 62.90%; and 17.30%, 11.40%. A substantial percent of DNA is unrecovered for all samples, but differs both between carpet type and organism. Therefore, it is necessary to consider extraction efficiencies not only for the characterization of qPCR and dPCR in analyzing indoor environmental samples, but also for calculating total microbial DNA concentrations in the environment, and for best estimating microbial exposures.

**P01.0410. Development of an In-Home Air Pollutant Sensor Platform and Implications for Community Use: Framework for Selection and Quality Control**

Abstract: Characterization of environmental exposures has been shaped by logistical, technological and financial constraints resulting in passive or integrated campaigns that do not allow fine-scale measurement of short-term events relevant to health. Recent advances allow for continuous monitoring of pollutants using comparatively small, inexpensive, real-time sensors. Such sensors have been widely used in occupational settings, but transitions to use in lower concentration environments present quality control challenges. For the Center for Research on Environmental and Social Stressors in Housing across the Life Course (CRESSH), we developed a multi-pollutant air sampling platform-environmental multi-pollutant monitoring assembly (EMMA)-for in-home measurements aiming to develop innovative methods for improved estimates in between-household variability in environmental exposures. Of one- and five-minute data collected using EMMA-carbon monoxide (CO), carbon dioxide (CO<sub>2</sub>), nitrogen oxides (NO<sub>x</sub>), particulate matter (PM<sub>2.5</sub>), temperature, relative humidity and noise-the following issues were identified and accounted for: inter-sensor variability, temperature effects and performance degradation. Gas sensors show notable initial performance (mean R<sup>2</sup>=0.99±0.005), but require constant performance scrutiny. Over 18 months, average CO sensor sensitivity decreased by 21% and NO & NO<sub>2</sub> by 36 & 30%, respectively, coinciding with differential signal at like concentrations over time. Modeling results from lab-based controlled experiments show NO & NO<sub>2</sub> data significantly biased at temperatures ≥93 & 90°F and below 40 & 50°F, respectively. Despite such issues, we achieved 97% data completeness. These findings may inform citizen science applications where various resources (e.g., calibration equipment, computer software) ensuring interpretable data may not be available. Our process of validating and maintaining EMMA may provide guidance for others seeking to develop and deploy such platforms.

## **P01.0420. A Mechanistic and Dynamic Air Quality Regression Model Featuring a Heterogeneous Wind Field**

Shimon Chen

*Shimon Chen<sup>1</sup>, - Yuval<sup>1</sup>, David M. Broday<sup>1</sup>*

*1. Civil and Environmental Engineering, Technion - Israel Institute of Technology, Pardesiya, Israel.*

Abstract: Air pollution exposure assessment is often performed through the use of regression models. These models work well due to their data-driven nature and the inherent high fit between observed and modeled values. However, they are often linear and lack the physics needed to assess air quality at a high temporal resolution. Although it has become common practice to incorporate the predictions of mechanistic models as an additional explanatory variable in land-use regression, the dispersion parameters themselves are not regressed in these cases. In this work, we developed a non-linear air quality regression model which is loosely based on Gaussian dispersion. This model incorporates ambient air quality measurements, emission rates from industrial stacks, GPS-based assessment of traffic volumes and a detailed (1 km) wind field as its inputs. The trajectories of emission "puffs" from each source are tracked throughout the study area and their effects on each location are calculated. At each half-hourly time-point an optimal set of 10 model parameters are computed via a non-linear least-squares regression process. These parameters include a "background" uniform concentration, linear coefficients for each source type, non-linear parametrizations of the dispersion standard deviations and a first-order kinetics reaction rate coefficient. The developed model enables us to perform air pollution exposure assessment at a high spatio-temporal resolution. This assessment can be performed at any location which has the model inputs available for it, and without any adjustments of the model formulation. Preliminary cross-validation results indicate a superior performance to both an older version of this model (which did not include a heterogeneous wind field) and spatial interpolation.

**P01.0430. Environmental Exposure Induced Metabolic Profiling Alterations in a Migration Panel between Los Angeles and Beijing**

**Abstract:** Migration provides individuals experiencing different environmental exposure episodes naturally, which offers a chance to attribute physiological response to certain exposure factors. To reveal the mechanism of health effect under environmental exposure, we designed a migration panel study between Los Angeles and Beijing, two cities with different exposure levels. Specifically, serum samples were collected from 27 summer school exchange students three times in total, one week before their departure (LA1), and at least four weeks respectively after their arrival to Beijing (BJ) and return to Los Angeles (LA2). The metabolic profiling was obtained through untargeted metabolomics approach with a high resolution TOF-MS. Combining with a series of statistical methods like Mann-Whitney test and Orthogonal partial least squares discriminant analysis, we screened prospective markers that changed significantly between LA and BJ. The significant decrease ( $p < 0.001$ ,  $FC > 1.2$ ) of indole and its precursor tryptophan in BJ reflected the induction of AhR and CYP by higher levels of pollutants. The decreased cortisol ( $p < 0.001$ ,  $FC > 1.5$ ) was potentially due to the accelerated consumption of CYP3A, supplying further evidence of enhanced CYP activity and related xenobiotics elimination in BJ. On the other hand, the increase of IL-8 and IL-10 from cytokine analysis suggested the oxidative stress during the process. A slightly higher level of uric acid ( $p < 0.01$ ,  $FC > 1.1$ ) along with its precursors implied the upregulation of antioxidation under the environmental exposure in BJ. Generally, this study illustrated that metabolomics offered an effective tool to assess the overall health impact under subchronic exposure.

## **P01.0440. Monitoring Chemical Contamination of Medical Air Produced On-Site in a Healthcare Institution Using Low-Cost Air Quality Sensors**

Hosna Movahhedinia

*3. Department of Laboratory Medicine and Pathobiology, Sunnybrook Research Institute, Toronto, ON, Canada.*

Abstract: Medical air is used in hospitals for patients suffering from a wide range of conditions. This air is typically produced by pressurizing outdoor air on-site and supplying it to patients through a lengthy piping system. Thus, it may contain chemical pollution from outdoor sources, line contamination, or technical problems within the compressor system. Hospitals in North America are mandated to meet medical air quality standards established by the United States Pharmacopeia (USP), yet its quality is often unmonitored. Further, USP limits for many pollutants common in ambient air are unspecified while specified limits for some pollutants are far higher than common ambient air quality standards even though this air is intended for potentially vulnerable individuals. Finally, patient exposure is not determined and thus generally unknown. In this study a sensor-based air quality monitor was used in conjunction with portable instruments to measure the concentration of CO, CO<sub>2</sub>, NO<sub>x</sub>, O<sub>3</sub>, black carbon (BC), and ultrafine particles (UFP). Simultaneous measurements were made at the outdoor intake to the compression system and at the patient-room end of pipelines at a Canadian hospital. The results show a strong association between outdoor air pollution and the medical air quality for some pollutants, based on correlation analysis. The concentrations of CO and CO<sub>2</sub> in the medical air were close to outdoor levels and followed the time-related changes in the outdoor concentrations. In contrast, the concentrations of NO<sub>x</sub> and O<sub>3</sub> were lower than outdoor levels, and BC and UFP levels were generally below detection limit. Although the chemical pollutant concentrations were below the USP standards, this study indicates that outdoor sources of air pollution can strongly influence the chemical contamination of medical air.

## **P01.0450. Impact of Smart Home Portable Air Purification on Average and Peak PM2.5 Concentrations in Small Urban Residences**

Erika Eitland

*Erika S. Eitland<sup>1</sup>, Memo Cedeno<sup>1</sup>, Jose Vallarino<sup>1</sup>, Piers MacNaughton<sup>1</sup>, Joseph G. Allen<sup>1</sup>*

*1. Environmental Health, Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

Abstract: Sensor-activated, dynamic portable air purifiers are a part of a growing market of smart home technologies aimed at improving energy efficiency and health. For vulnerable populations such as children, elderly and individuals with a pre-existing condition, air purification may reduce daily exposure to harmful concentrations of fine particles. Some new air purifiers are sensor activated such that filtration is triggered by air quality conditions in the space; however, the effectiveness of these 'smart home' purifiers compared to traditional air purification has not been evaluated in a real-world setting. In summer 2017, a crossover study was completed in small urban residences (n=32), which compared the change in continuous particulate matter less than 2.5 microns in diameter (PM2.5) concentrations across three intervention arms: 1) No Air Purification, 2) Smart Home Purification and 3) Continuous Purification. Overall, continuous purification significantly reduced average PM2.5 compared to baseline and smart home conditions by 1.171  $\mu\text{g}/\text{m}^3$  and 1.210  $\mu\text{g}/\text{m}^3$  respectively. However, the average duration participants were exposed to concentrations above 30  $\mu\text{g}/\text{m}^3$ , the activation threshold for the device used in the study, was shortened by 60.8 minutes and 43.8 minutes with Smart Home purification compared to baseline and continuous filtration, respectively. The implication of these findings is that Smart Home purification can reduce peak exposures to PM2.5, but may lead to higher cumulative exposures at lower levels compared to continuous filtration. As a result, Smart Home purification may be best suited to reduce exposures during acute PM2.5-emitting events such as cooking or rush hour traffic.

**Abstract:** Background: The HAPIN four-country randomized trial seeks to evaluate the effects of liquefied petroleum gas stoves and fuel distribution intervention on health outcomes. Adequate assessment of personal PM<sub>2.5</sub> exposure is critical for both understanding intervention effectiveness and building exposure-response relationships. Since standard gravimetric pump and cyclone/impactor approaches for personal PM<sub>2.5</sub> assessment are heavy, noisy, and bulky, they are unsuitable for children and burdensome to adults. In a pilot study, we compared the performance of a next-generation exposure monitor [Enhanced Children's MicroPEM (ECM), RTI International, Raleigh, NC] to standard gravimetric methods. Methods: We co-located standard gravimetric pumps and cyclone/impactors with ECMs to obtain 24- and 48-hour kitchen PM<sub>2.5</sub> concentrations and corresponding personal exposures in Guatemala, India, Peru, and Rwanda in homes with a range of exposures. Specific sampling approaches varied across centers due to logistics. Bland-Altman plots were used to assess agreement in mean PM<sub>2.5</sub> between devices. Results: Using 124 personal samples and 102 kitchen samples, average PM<sub>2.5</sub> concentrations measured by standard gravimetric methods and the ECM were 97.7 µg/m<sup>3</sup> (range: 2.1-585.9 µg/m<sup>3</sup>) and 108.5 µg/m<sup>3</sup> (range: 9.6-516.5 µg/m<sup>3</sup>), respectively. The mean difference between the ECM and standard gravimetric approach was -10.8 µg/m<sup>3</sup> (95% CI: -151 to 129 µg/m<sup>3</sup>). Lastly, there was no substantial proportional bias in assessment of PM<sub>2.5</sub> concentration at any level [mean difference 0 to 49.9 µg/m<sup>3</sup>: -20.1 µg/m<sup>3</sup> (95% CI: -96.5 to 56.2 µg/m<sup>3</sup>); mean difference 50.8 to 99.4 µg/m<sup>3</sup>: -22.2 µg/m<sup>3</sup> (95% CI: -163.2 to 118.7 µg/m<sup>3</sup>); mean difference 107.2 to 585.9 µg/m<sup>3</sup>: 10.95 µg/m<sup>3</sup> (95% CI: -196.6 to 218.5 µg/m<sup>3</sup>)]. Conclusions: Preliminary results indicate that PM<sub>2.5</sub> concentrations evaluated with the ECM personal exposure monitor are in agreement with those obtained with standard gravimetric samplers and cyclone/impactors.

**P01.0470. Personal Sensors and In Situ Interviews to Assess Pollution Exposure in a Busy Intersection of Mexico City**

Yazmin Valdez-Torres

*Yazmin J. Valdez-Torres<sup>1</sup>, Aron Jazcilevich Diamant<sup>2</sup>, Patricia Segura Medina<sup>3</sup>, Antonio Suarez Bonilla<sup>4</sup>, Bertha E. Mar Morales<sup>2</sup>, Carlos A. Chaves Sanches<sup>5</sup>, Olmo Zavala-Romero<sup>6</sup>*

Abstract: Personal sensors measuring CO and PM2.5 concentration levels were displayed to assess the most polluted areas in a busy intersection of Mexico City. Using Geographical Information System and proper statistical handling, exposure levels to traffic-related air pollution were localized in time and space. Concurrently, a questionnaire was applied in situ to detect respiratory disease symptoms in people that work or pass by the intersection. The methodology employed allowed comparison (in terms of pollution exposure) of pedestrian routes at street level, and long term daily exposure effects. Results found that 91 % of people who use the intersection as a workplace presented chronic respiratory diseases, and also high pollution emitters were identified. The study led to recommendations on emission vigilance, and reduction of pedestrian exposure by street layout design changes.

## **P01.0480. Using Arduino Air Sensors to Create STEM Interest in Under-Represented Populations**

Teresa Jarvis

*Teresa Jarvis<sup>1</sup>, Kabindra Shakya<sup>1</sup>, Meghan Conway<sup>1</sup>*

*1. Geography and the Environment, Villanova University, Abington, PA, United States.*

Abstract: Air pollution is a cause for concern on a global scale because of the continuing health impacts. The purpose of this study is to raise awareness of local air pollution, and incorporate STEM training to students in the Wissahickon School District, Pennsylvania. The negative effects include respiratory, cardiovascular, cardiopulmonary and reproductive systems, and even cancer. The effects of particulate matter exposure may be greater on children compared to adults, because of the children's rapid growth rate. In addition to particulate matter collection, this study also included the development of students to engineering, coding and data collection. Another component to this study was leadership development in under-represented STEM populations. Personal air sensors can be used to monitor short-term exposure using fixed-site monitoring (FSM). High school students used the Arduino air sensor to collect local data in Ambler, PA. These inexpensive air sensors were calibrated with research grade air quality monitors. The initial building team was comprised of students who are under-represented in the STEM fields. The head team built and problem-solved two initial models. This team then taught twenty other students of varying backgrounds to build the Arduino air sensors. Eighty-five high school students collected data using the sensors. The data was used to inform students about air pollution and raise their awareness of the impact of air pollution exposure. Implementing less expensive equipment would enable projects to occur in areas where data needs to be collected but the air sensors are considered too expensive.

**P01.0490. Merging Low-Cost and Conventional Air Monitoring Methods to Investigate Biomass Burning in a Highly Impacted, Multi-Cultural Rural Setting**

Orly Stampfer

*Orly Stampfer<sup>1</sup>, Elena Austin<sup>1</sup>, Terry Ganuelas<sup>2</sup>, Jessica Black<sup>3</sup>, Edmund Seto<sup>1</sup>, Maria I. Tchong-French<sup>1</sup>, Catherine Karr<sup>1</sup>*

- 2. Yakama Nation Environmental Management Program, Toppenish, WA, United States.*
- 3. Heritage University, Toppenish, WA, United States.*

Abstract: The lower Yakima Valley of Washington State is a rural area home to communities including Latinx farmworker families, the Confederated Tribes and Bands of the Yakama Nation, and Native Americans of other tribes. Episodic poor air quality impacts this region, partly due to a mixture of different particulate matter (PM) sources, including residential wood smoke, agricultural biomass burning, and diesel emissions. We investigated air quality using low-cost and conventional approaches. University of Washington partnered with Yakama Nation Environmental Management Program and Heritage University to collect data at a tribal air monitoring site from 1/29/18-3/12/18 using a laser based, low-cost, 5-bin particle counter and a 5-wavelength aethalometer (MA200 Aethlabs). We used an established indicator for biomass burning and wood smoke: Delta-C, the difference in absorbance of the aethalometer at 375nm-880nm. We estimated an indicator for soot and aged diesel using the ratio of the mass at 375 vs. 880, where a ratio closer to 1 indicated more soot and aged diesel. A co-located tribal beta-attenuation monitor measured hourly PM<sub>2.5</sub> mass. Over 43 days, the daily PM<sub>2.5</sub> mean was 7.5 µg/m<sup>3</sup> (SD 4.7 µg/m<sup>3</sup>, range 1.3-20.7 µg/m<sup>3</sup>). Hourly Delta-C mean was 0.27 µg/m<sup>3</sup> (IQR 0.34 µg/m<sup>3</sup>). For 11 instances, the hourly ratio of Delta-C to PM<sub>2.5</sub> mean was >1/7.5, indicating episodes of high biomass burning. The hourly ratio of the mass at 375 vs. 880 mean was 1.5 (IQR 0.95). Nighttime mean PM<sub>2.5</sub> (8.8 µg/m<sup>3</sup>) and Delta-C (0.39 µg/m<sup>3</sup>) were greater than daytime PM<sub>2.5</sub> (5.9 µg/m<sup>3</sup>) and Delta-C (0.16 µg/m<sup>3</sup>). The mean ratio of Delta-C to PM<sub>2.5</sub> mass was greater at night (0.038) than daytime (0.027). Daytime correlations varied between Delta-C and PM<sub>1</sub> (0.33), PM<sub>2.5</sub> (0.28), and PM<sub>10</sub> (0.21) and nighttime correlations were all 0.79. This study shows a promising example of merging data from novel low-cost instruments with existing technology that can inform a community about their exposure to biomass burning.

## **P01.0500. Developing a Community-Engaged Low-Cost Air Monitoring Network in Seattle, Washington**

Nancy Carmona

*Nancy Carmona<sup>1</sup>, Roxanne Garcia<sup>3</sup>, Natalia Kowalchuk<sup>3</sup>, Edmund Seto<sup>1</sup>, Lianne Sheppard<sup>2</sup>, Vanessa Galaviz<sup>1</sup>*

*1. Environmental and Occupational Health Sciences, University of Washington, Seattle, WA, United States.*

*2. Biostatistics / Environmental and Occupational Health Sciences, University of Washington, Seattle, WA, United States.*

*3. School of Public Health, University of Washington, Seattle, WA, United States.*

Abstract: The Community Air Monitoring in Puget Sound (CAMPS) network is being developed as part of a community-engaged research study to provide neighborhood level air quality data to groups that are concerned about air quality. The goal of this study is to collect and provide air quality data to residents in order to support individual and community actions to reduce exposures to improve their health. In addition to university academics, partners in the study include child care centers, community clubs, and youth clubs. Partners were recruited via email, phone, or in-person canvassing. Groups were invited to participate if they reside in Seattle, were near major highways or roadways, and were concerned about air quality. The community engagement framework of this study has opportunities for community partners to be an integral part the study design, including selecting monitoring sites, data collection, and report back process. A comprehensive needs assessment was completed through a community survey, key informant interviews, and discussions with community members and community steering committees. Findings on neighborhood differences will be presented from the ongoing monitoring network that uses 10 low-cost air monitors to measure real-time PM<sub>2.5</sub> (particulate matter with aerodynamic diameter <2.5 μm), nitrogen dioxide, carbon monoxide and ozone data. To encourage engagement, air monitoring data are shared with the public in the form of a real-time data website and monitoring reports. Evaluation at the conclusion of the study will be crucial in determining if the project goals are attained and in identifying improvements for future community-engaged air monitoring studies. Preliminary results in our monitoring network have found mean background PM<sub>2.5</sub> at 8.01 ug/m<sup>3</sup> and 13.47 ug/m<sup>3</sup> near roadways. This submission will present the results of the needs assessment, discuss motivating factors related to community participation in CAMPS, and summaries of CAMPS air monitoring.

## **P01.0510. A Mobile Health Approach to Improving Personal Exposure Assessment: Using Mobile Sensor Data and Machine Learning to Predict Key Microenvironments**

Hua Hao

*Hua Hao<sup>1</sup>, Sandrah Eckel<sup>1</sup>, Eleanne van Vliet<sup>1</sup>, Kenan Li<sup>1</sup>, Frank Gilliland<sup>1</sup>, Rima Habre<sup>1</sup>*

*1. Keck School of Medicine, University of Southern California, Los Angeles, CA, United States.*

**Abstract:** Background: The assessment of personal exposure to air pollution is a critical component of environmental epidemiology, but the majority of current studies rely on diary-reported time-activity data which suffer from recall bias and do not accurately capture individuals' key microenvironments encountered in daily life. Recent advance in mobile sensing technologies combined with machine learning approaches have the potential to improve personal exposure assessment. Aims: To predict time-resolved activity in key microenvironments (indoor, outdoor and in transit) based on passively collected smartphone sensor data and evaluate the performance using machine learning algorithms. Methods: The Android application 'AndroSensor' was used to passively log 8 environmental sensors on a Samsung S4 smartphone every 10 seconds. Scripted activities were annotated over five days. Data was transformed and missing values imputed where possible. We considered the task of microenvironment prediction as a classification problem and compared the performance of a Random Forest (RF) algorithm to four other methods: K-nearest neighbors (KNN), multinomial logistic regression (MLR), Naïve Bayes (NB), and decision tree (DT). We used 10-fold cross-validation to evaluate prediction ability. Feature importance was calculated based on node impurity of the random forest. Results: We collected a total of 21,296 observations on 31 different features. The highest accuracy achieved was 98.61% for RF, followed by 95.65% for KNN, 89.48% for MLR, 85.01% for NB and 92.50% of DT. The following five features were consistently ranked as most important: sound level, speed, temperature, total satellites in range, and location accuracy. Conclusion: Our RF algorithm outperforms all the other 4 algorithms and achieves a high accuracy. Our developed model can be used to improve existing personal air pollution exposure assessment in conjunction with spatiotemporal estimates of ambient air pollution.

## **P01.0520. Estimation of Individual Based Exposure Assessment for Indoor Radon Using the Propensity Score Method**

Hayon Michelle Choi

*Hayon Michelle Choi<sup>1</sup>, Dae Ryong Kang<sup>2</sup>*

*1. Seoul National University, Seoul, Korea (the Republic of).*

*2. Wonju College of Medicine , Yonsei University , Wonju, Korea (the Republic of).*

**Abstract:** Epidemiologic studies are the best way to examine the risk and association between residential radon exposure and lung cancer. Previous studies suggest that exposure to residential radon may contribute to the incidence of lung cancer in the general population and varying residential conditions could also affect the relationship of radon exposure and lung cancer. Many studies considering association were conducted worldwide, however few studies have shown the causal inference. To investigate the causal association between residential radon and lung cancer based on Korea living conditions, we conducted a study using propensity score method in Korea. This study includes data from 4 hospitals (Ajou university, Severance, Wonju severance, Seoul-asan) for the treatment group (Lung-cancer patients) and from 4 community-based cohorts (Seoul CMERC, Wonju KoGES, Ansung KoGES, Kyeongnam Namgaram) for the control group (Not lung-cancer patients). Total 440 (650 treatments and 5624 controls) were included in the data. Considering age, sex, smoking status, and socio-economic factors the propensity score was analyzed. The propensity score method we used was propensity score matching. The characteristic differences for covariates before and after propensity score matching is shown. Also, the distribution difference between raw data and matched data is represented in Figure 1. The propensity score distribution in the control group was matched to the treated group. The odds ratio for using propensity score matching and without propensity score were demonstrated in Figure 2. This study examined the causal association between indoor radon level and lung cancer in Korea. However, due to lack of data further study is needed after data completion.

## **P01.0540. Evaluating Association between Air Pollution and Cardiovascular Outcomes Using Smartphone Particle Sensors and Wearable Technologies in Children**

Chris Lim

*1. New York University School of Medicine, New York, NY, United States.*

*2. SUNY Albany, Albany, NY, United States.*

**Abstract:** Introduction: Recent development of both portable air pollution particle sensors and wearable technologies offers unique opportunities to study the real-time association between exposure and cardiopulmonary outcomes. We explored potential application of two technologies, AirBeam2 and Hexoskin smart shirt in a group of children. Methods: Elementary school aged children (N=12) in Albany, NY, are being equipped with particle sensor 'AirBeam2' (which measures PM1, PM2.5, and PM10), and a HexoSkin smart t-shirt (which measures heart rate, heart rate variability, breathing rate, ventilation) for a 1 week period, during all waking hours. Results: We will consider performance of AirBeam2 with stationary monitors, both a real-time instrument and integrated gravimetric filter system, previously placed within the classroom. The real-time relationship between exposure to PM and changes in heart rate variability, relative to baseline, will be measured and modeled using linear mixed models. We will also calculate lung deposited dose for PM using the measured lung function metrics from HexoSkin. Conclusion: Unique challenges were observed and experienced by researchers in this study assessing potential deployment of novel sensors in young children to study air pollution-health relationship. Preliminary results suggest that increased exposure to particulate matter exposure can potentially affect adversely cardiovascular outcomes among children.

## **P01.0550. Method Suggestion of Predicting the Exposure to Residential Indoor Air Pollutants Using Time-Activity Patterns and Outdoor Air**

Abstract: Most people may be affected by indoor air quality at home since it is where they spend most of their time. Although air pollutants (APs) concentrations such as particulate matter, SO<sub>2</sub>, NO<sub>2</sub>, CO, and O<sub>3</sub> is provided through ambient fixed monitoring system, it could be different from actual exposure concentrations because it has limitations such as distance and staying in indoor environments. The purposes of this study were to predict the concentrations of Indoor APs (IAPs) and to assess exposures at home considering indoor sources and house residential time of people by analyzing time-activity patterns including questionnaire. To estimate IAPs concentrations, we applied the concentration of outdoor air pollutants by measurements or atmospheric modelling, and indoor air quality model to PM, NO<sub>2</sub>, CO concentrations with indoor sources, and Indoor/Outdoor ratio acquired from previous studies, and to SO<sub>2</sub> and O<sub>3</sub> concentrations without indoor sources. The concentrations of APs were acquired from ambient fixed monitoring system. And the concentrations of IAPs were measured in houses with sensor instruments of particulate matter by adjusting gravimetric method, and exposure to IAPs were estimated. Residential time at home was more than about 90% their times. Results of measurements of sensor indicate increased concentrations of IAPs with indoor sources from cooking, cleaning and smoking than usual (no behavior) and concentrations of IAPs with indoor sources increase as number of the behavior increase. Sub-populations such as the old and housewives might be more likely to be affected by house indoor air because they spend most of their time at home. We predicted the concentrations of IAPs and assessed exposures at home to IAPs by modelling and analyzing time-activity patterns including questionnaire. These results will be expected to provide basis for preparing guidelines for prevention of diseases caused by house IAPs

## **P01.0551. Towards Continuous Domain Models in Spatial Epidemiology**

Abstract: One of the goals of spatial epidemiology is to identify areas with elevated disease risk. Such analyses are often hampered by the limited geographical resolution of the available data. When data are aggregated into spatial units, conditional autoregressive (CAR) models are commonly used. When data are available at higher resolution (e.g. geocodes), log-Gaussian Cox processes (LGCPs) provide a more natural modelling framework. In theory, LGCPs should perform better, but do they? We simulated data mimicking childhood leukaemia incidence in the Canton of Zurich in Switzerland (n=334 during 1985-2015). Geocoded locations of residence were available for the entire population. We randomly sampled case locations from these data under different risk scenarios. We considered 39 scenarios varying the shape of the true risk function (constant, step-wise, exponential decay), size of the high-risk areas (1, 5 and 10 km radii), risk increase in the high-risk areas (2 and 5-fold) and the number of cases (n, 5n and 10n). We compared the ability of the models to recover the true risk surface using the root mean integrated squared error (RMISE) and their ability to identify high-risk areas using area under the ROC curve (AUC). CAR models recovered the step-wise true risk surface with lower error across all scenarios (range of median RMISE across scenarios: 0.05-0.25) compared to LGCPs (median RMISE: 1.80-37.2). For exponential decay risk surfaces, however, LGCPs performed better (median RMISE: 1.70-20) compared to CAR (median RMISE: 1.80-32) in almost all scenarios. The ability to detect high-risk areas was higher for LGCPs (median AUC: 0.81-1) compared to the CAR model (median AUC: 0.65-0.93) across almost all scenarios. Our simulation study suggests that, under realistic scenarios, continuous domain models outperform discrete domain models in estimating risk surfaces and identifying high-risk areas. This argues for moving towards continuous domain models in spatial epidemiology.

**P01.0552. Temporal Trend of Exposures to Polycyclic Aromatic Hydrocarbons and Bisphenol A during 2012-2016: A Comparison between China and the United States**

Yan Lin<sup>1</sup>, Xinghua Qiu<sup>2</sup>, Yifang Zhu<sup>1</sup>

1. *Environmental Health Science, UCLA, Los Angeles, CA, United States.*

2. *Environmental Science, Peking University, Beijing, Beijing, China.*

**Abstract:** At national scales, changes in human exposures to environmental chemicals are largely driven by government's regulatory actions. Due to the inter-country variations in social, cultural, and economic conditions, the temporal trends of human exposures to chemicals are likely to be different among countries. To test this hypothesis, urine samples (n=350) were collected from four panels of summer exchange students (n=45) between University of California, Los Angeles (UCLA, in Los Angeles, United States) and Peking University (in Beijing, China) in 2012, 2014, 2015, and 2016. The urinary metabolites of two groups of environmental pollutants, namely polycyclic aromatic hydrocarbons (PAHs) and bisphenol A (BPA) were measured. In each year, exposures to PAHs and BPA were both significantly higher in Beijing than in Los Angeles ( $p < 0.05$ ). From 2012 to 2016, PAHs exposures didn't change in Los Angeles, but continuously decreased in Beijing ( $p < 0.01$ ) which was probably due to the drastic reduction in PAHs emissions from residential, commercial, and industrial sources in China. BPA exposures, by contrast, continuously decreased in Los Angeles ( $p < 0.001$ ), but didn't change in Beijing. This is likely due to extensive efforts from government and manufacturers to phase out BPA in the United States and calls for actions to regulate BPA in China. Overall, the observed temporal trends of PAHs and BPA exposures reflect the difference in pollution controlling measures between the two countries.

8. *University of Toronto, Toronto, ON, Canada.*
9. *McGill University, Montreal, QC, Canada.*

**Abstract:** Background: Ambient air pollution exposure during early life has recently been associated with diabetes incidence in children. However, little is known regarding critical exposure windows and if exposure to greenness could modify these associations. This study sought to assess the relationship between selected air pollutants (NO<sub>2</sub>, PM<sub>2.5</sub>, O<sub>3</sub>, and Ox [oxidant capacity]) and the incidence of paediatric diabetes. Methods: Our cohort consisted of 754,698 mother-infant pairs occurring between 2006 and 2012 in the province of Ontario, Canada. Diabetes incidence was ascertained using population-based health administrative data with a validated algorithm. The cohort was followed until 2015. Temporally adjusted exposure to NO<sub>2</sub>, PM<sub>2.5</sub>, and O<sub>3</sub> was estimated using satellite-based regression, land-use regression, and a fusion-based approach, respectively, and was assigned to subjects' residential postal codes during pregnancy. Ox was calculated as the redox-weighted average of O<sub>3</sub> and NO<sub>2</sub>. Satellite-derived normalized difference vegetation index (NDVI) was used to represent the amount of green vegetation at a 250m buffer across Ontario. Associations between total pregnancy, trimester specific, and early life exposures to ambient air pollutants and childhood diabetes incidence up to age 6 were estimated using Cox regression models.

**Results:** 1,094 children with diabetes were identified. Each IQR increase in O<sub>3</sub> and Ox exposures in the second trimester of pregnancy were associated with hazard ratios of 1.36 (95% CI: 1.07-1.73) and 1.45 (95% CI: 1.05-1.81), respectively. These relationships exhibited linear shapes, and exposure to greenness was found to have a protective modifying effect (p-interaction ≤ 0.04). There were no other positive associations observed for other pollutants and other time periods.

**Conclusions:** Air pollution, especially O<sub>3</sub> and Ox, was linked to increased diabetes risk in children. Exposure to greenness during pregnancy appeared to attenuate these associations.

**P01.0570. Pervasive Developmental Disorder and Particulate Matter Air Pollution before, during and after Pregnancy: A Case-Cohort Study within the National Infant Medical Check-Up Cohort**

Jueun Lee

*Jueun Lee<sup>1</sup>, Suejin Kim<sup>1</sup>, Chul Woo Lee<sup>1</sup>, Eui Jung Kim<sup>2</sup>, Ha Eunhee<sup>2</sup>*

*1. Environmental Health Research Department, National Institute of Environmental Research, Incheon, Korea (the Republic of).*

*2. College of Medicine, Ewha Womans University, Seoul, Korea (the Republic of).*

**Abstract:** Background: There is increasing interest in the effect of air pollution in children's neurodevelopment but the evidence remains inconclusive. This study investigated the association of particulate matter air pollution exposure and pervasive developmental disorder (PDD) throughout the first 6 years of life. Methods: We conducted a case-cohort study of participants born in Korea in the year of 2008 who underwent at least the first medical check-up provided by The National Health Insurance Database until December 31, 2013. The study assessed all 761 subjects who were diagnosed with PDD till the age of six along with a subcohort of six times of that size, 5,178 subjects, selected as a 2.5% random sample of the full target cohort. Diagnosis of PDD was based on the payment and treatment data at the clinic. Daily averages of PM with diameters  $\leq 2.5 \mu\text{m}$  (PM<sub>2.5</sub>) and  $\leq 10 \mu\text{m}$  (PM<sub>10</sub>) were predicted from a spatiotemporal model for South Korea and linked to residential addresses. A weighted Cox proportional hazards model was used to estimate adjusted hazard ratio (aHR) with 95% confidence intervals (CI) for PDD in infants exposed to particulate matter air pollution. Results: A significant association was found between 10  $\mu\text{g}/\text{m}^3$  increment in the PM<sub>2.5</sub> concentration and PDD with adjusted RR of 1.12 (95% CI 1.04-1.20) among the participants with the same address before and after pregnancy. Associations with PM<sub>2.5</sub> exposure 9 months before or after the pregnancy were weaker in independent models and when all periods were included, whereas the association with the 9 months of pregnancy remained. The association between PDD and PM<sub>2.5</sub> was stronger for exposure during the third trimester (OR = 1.32 per IQR increase in PM<sub>2.5</sub>; 95% CI: 1.16, 1.49) than during the first two. There was little association between PM<sub>10</sub> and PDD. Conclusions: The results suggest higher maternal exposure to PM<sub>2.5</sub> during pregnancy, particularly the third trimester, was associated with the risk of developing PDD.

**P01.0580. Fine Particle (PM2.5) and Preterm Birth from 7 Metropolitan Cities Study, Korea, 2015-2016**

Eun-Hee Ha

*youngrin Kwag<sup>1</sup>, min-ho kim<sup>1</sup>, Eun-Hee Ha<sup>1</sup>, Shinhee Ye<sup>1</sup>, Jongmin Oh<sup>1</sup>, Seulbi Lee<sup>1</sup>, Ji-young Lee<sup>1</sup>*

**Abstract:** Particulate matter contributing to low birth weight and preterm birth are of great concern because of the well-known relation of birth weight to infant mortality and adverse effects in later life. We examined the associations between fine particle (PM2.5) during the pregnancy and low birth weight and preterm birth for a 2-year period (January 2015 to December 2016) in 7 metropolitan cities, Republic of Korea. We obtained birth certificates in the 7 metropolitan cities from the Korean National Birth. The associations were evaluated with a logistic regression adjusting for gestational age, maternal age, parity, birth month, and infant sex. We determined the first and third trimester (TR) periods and ascertained birth weight and most of the covariates included in this study. PM2.5 data were obtained from the Ministry of Environment. Of 406,243 births registered, we included 176,842 births which are in 7 metropolitan cities, 22-42 weeks, and 500-5000g in the final analysis. When we consider first TR and third TR period, respectively, the risk of pre-term (gestational age < 37 weeks) by 10 µg/m<sup>3</sup> increase PM2.5 concentrations for first TR period was 1.066 (95% CI: 1.029-1.104) and for third TR period was 0.992 (95% CI: 0.953-1.034). However, we consider first TR and third TR period, the risk of pre-term (gestational age < 37 weeks) by 10 µg/m<sup>3</sup> increase PM2.5 concentrations for first TR period was and for third TR period was 0.983 (95% CI: 0.943-1.025). When we entered concentrations of PM2.5 during the first and third TR of pregnancy together in the model, the relative risk of low birth weight for PM2.5 during the first TR of pregnancy remained constant (OR: 1.058, 95% CI: 1.020-1.097). However, in the third TR, the risks changed toward the null for all pollutants (OR: 0.983, 95% CI: 0.943-1.025). PM2.5 concentrations in the first TR of pregnancy period are risk factors for preterm birth. **Keywords :** PM2.5., low birth weight, preterm birth, 7 metropolitan cities, Korea

**P01.0581. Indoor Air Pollution and Reduced Lung Function in Biomass Exposed Women:  
A Cross Sectional Study in Pune District, India**

Rasmila Kawan

*Rasmila Kawan<sup>1</sup>*

*1. Climate change and health, Heidelberg Institute of Public Health and International Center for Integrated mountain development, Lalitpur, Nepal.*

Abstract: Indoor air pollution especially from the use of biomass fuels, remains a potentially large global health threat. The inefficient use of such fuels in poorly ventilated conditions results in high levels of indoor air pollution, most seriously affecting women and young children. The main aim of this study was to measure and compare the lung function of the women exposed in the biomass fuels and LPG fuels and relate it to the indoor emission measured using a structured questionnaire, spirometer and filter based low volume samplers respectively. This cross-sectional comparative study was conducted among the women (aged > 18 years) living in rural villages of Pune district who were not diagnosed of chronic pulmonary diseases or any other respiratory diseases and using biomass fuels or LPG for cooking for a minimum period of 5 years or more. Data collection was done from April to June 2017 in dry season. Spirometer was performed using the portable spirometer to determine the lung function over Forced expiratory volume. The primary outcome variable was forced expiratory volume in 1 second (FEV1). Secondary outcome was chronic obstruction pulmonary disease (post bronchodilator FEV1/ Forced Vital Capacity (FVC) < 70%) as defined by the Global Initiative for Obstructive Lung Disease. Potential confounders such as age, height, weight, smoking history, occupation, educational status were considered. Preliminary results showed that the lung function of the women using Biomass fuels had comparatively reduced lung function than the LPG users . The mean PM 2.5 mass concentration in the biomass user's kitchen was higher than in the LPG user's kitchen. Black carbon amount was found higher in the biomass users than LPG users . Therefore, there is an urgent need to adopt various strategies to improve indoor air quality.

## **P01.0582. Indoor Nitrogen Dioxide in Homes with Biomass Cookstoves before and after a Gas Stove Intervention**

Josiah Kephart

*1. Environmental Health and Engineering, Johns Hopkins University, Baltimore, MD, United States.*

*2. Division of Pulmonary and Critical Care, Johns Hopkins University School of Medicine, Baltimore, MD, United States.*

**Abstract:** Emissions from biomass-fueled cookstoves are the largest environmental contribution to the global burden of disease, responsible for 2.6 million deaths annually. A transition from biomass to liquified-petroleum gas (LPG) cookstoves has been proposed as a global public health intervention. While this transition seems likely to reduce fine particulate matter and carbon monoxide, very little is known about cookstove-related emissions of nitrogen dioxide (NO<sub>2</sub>), a threat to respiratory health. Assessing exposure to NO<sub>2</sub> from biomass and LPG cookstoves is essential to understand the public health risks posed by biomass cookstoves and inform the current promotion of LPG as a healthier alternative to biomass fuel. This study aims to 1) quantify NO<sub>2</sub> exposure from biomass cookstoves and 2) assess changes in NO<sub>2</sub> exposure after the transition from biomass to LPG cookstoves. We will measure NO<sub>2</sub> concentrations in 100 kitchens with biomass cookstoves in rural Puno, Peru. Concentrations will be sampled by direct-reading instruments at one-minute intervals for 48 hours, allowing us to quantify both daily mean concentrations and short-term concentration peaks associated with cooking events. To assess the effect of transitioning from biomass to LPG on kitchen NO<sub>2</sub> concentrations, we will randomize 50 of these households to receive free LPG stoves and fuel and 50 households to serve as a control. We will measure NO<sub>2</sub> concentrations three months post-intervention. In our study setting, homes with biomass cookstoves experienced daily NO<sub>2</sub> concentrations [48-hour mean (sd): 139 ppb (92), n=99] well above the WHO indoor annual guideline (21 ppb). Acute exposures were also elevated, as 26% of kitchen-hours [1-hour mean (sd): 139 ppb (252), n=2376 hours] were above the WHO indoor hourly guideline (105 ppb). Transitioning from biomass to LPG cookstoves reduced daily NO<sub>2</sub> concentrations by 40%, however these concentrations [mean (sd): 73 ppb (47), n=40] remain above the WHO annual guideline (21 ppb).

**P01.0583. Association between Air Pollution Exposure and Inflammation in Chronic Obstructive Pulmonary Disease Patients in Beijing, China**

Yuan Yao

*Xi Chen<sup>1</sup>, Yuan Yao<sup>1</sup>, Wu Chen<sup>1</sup>, Chengli Que<sup>2</sup>, Xiaoying Li<sup>1</sup>, Mei Zheng<sup>1</sup>, Lina Zhang<sup>3</sup>, Hanxiyue Zhang<sup>1</sup>, Xinghua Qiu<sup>1</sup>, Tong Zhu<sup>1</sup>*

*2. Peking University First Hospital, Peking University, Beijing, China.*

*3. Beijing Xicheng District Shichahai Community Health Center, Beijing, China.*

**Abstract:** Background/Aim: Chronic obstructive pulmonary disease (COPD), characterized by chronic inflammation, is one of the leading causes of death worldwide. The biological mechanism of inflammation associated with exposure to air pollution in COPD patients are not well understood. To elucidate the association between air pollution exposure and inflammatory response in COPD patients, 135 subjects, including 53 stable COPD patients and 82 healthy controls, were recruited in a panel study in Beijing, China. Methods: Fractional exhaled nitric oxide (FeNO) and serum cytokines were repeatedly measured from each subject during 4 visits. Levels of air pollutants, including mass and number concentration of fine particulate matter, mass concentration of black carbon/organic carbon (OC)/elemental carbon/ heavy metals, gaseous pollutants, were online monitored. Linear mixed-effect models were used to estimate the different inflammatory responses to the air pollution exposure between COPD patients and healthy controls. Results: Exposures to SO<sub>2</sub>, OC and ultrafine particles (UFP) were positively associated with the levels of FeNO, which were more significant in COPD patients. Increases in levels of IL-6 associated with CO, Mn and Cu exposures in COPD patients were significantly higher than those in healthy controls. Exposures to UFP and Acc were associated with increasing levels of IL-15, which were more significant in COPD patients. Exposure to CO was associated with decreasing levels of IL-1 $\beta$ , IL-4, IL-10, IL-13 and IL-17A in healthy controls, which was not observed in COPD patients. Conclusions: In summary, COPD patients are susceptible to the acute respiratory inflammation associated with air pollution exposure, and their capabilities to regulate inflammation are weaker than healthy controls. Acknowledgement: The study was funded by National Program on Key Basic Research Project (2015CB553401). We thank all the volunteers, students and staff involved in COPD for their contributions.

## **P01.0584. Leveraging Real-Time Data to Identify Determinants of Indoor PM2.5 Exposure Disparities at the Community-Level**

MyDzung Chu

*MyDzung T. Chu<sup>1</sup>, Sara Gillooly<sup>1</sup>, Jose Vallarino<sup>1</sup>, Lacy Reyna<sup>1</sup>, Gary Adamkiewicz<sup>1</sup>*

*1. Environmental Health, Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

**Abstract:** Elucidating determinants of increased indoor exposures is critical to alleviating exposure and health disparities. PM2.5 is a key determinant of indoor air quality and cardiorespiratory health. As part of the Center for Research on Environmental & Social Stressors in Housing across the Life Course (CRESSH), we investigated indoor PM2.5 sources within small spatial and temporal scales. We recruited 72 households in Chelsea, MA from 6/2016-8/2017. We collected in-home and outdoor PM2.5, housing, and activity data across 1 week for 2 seasons using a real-time sensor platform, visual assessments, and surveys. We assessed predictors of indoor PM2.5 by season using linear mixed-effect models accounting for non-linear effects of time and outdoor PM2.5, race/ethnicity, rent status, housing type, occupancy, and kitchen vent use. Households were predominantly Hispanic/Latino (49%), renters (54%), & low-income (<\$50K) (54%). Mean indoor PM2.5 was 10.3 $\mu\text{g}/\text{m}^3$  (SD: 60.2) for summer and 9.6 $\mu\text{g}/\text{m}^3$  (30.2) for winter. Across seasons, significant predictors were time of day ( $\beta=1.16-2.18$ ,  $p<0.01$ ) & outdoor PM2.5, which was more strongly associated in summer ( $\beta\geq 1.43$ ,  $p<0.02$ ). In summer, use of gas stoves (vs. electric) ( $\beta=2.05$ ) & having visitors who smoked ( $\beta=4.55$ ) were also significant ( $p<0.04$ ). In winter, any weekend cooking ( $\beta\geq 3.23$ ), residential smoking ( $\beta=2.72$ ), & weekday status ( $\beta=1.07$ ) were also significant ( $p<0.02$ ). Risk factors varied socio-demographically: renters were more likely to smoke (8.5x), homeowners more often had gas stoves (1.3x), & low-income households cooked longer periods ( $\geq 60$  min.: 1.72x). Our findings underscore the value of real-time data to identify time-varying sources and contributors of indoor PM2.5. Seasonal effects are likely driven by changes in meteorology, housing conditions, and activity that affect air exchange. The socioeconomic patterning of risk factors, much of which is modifiable, implicate targets for reducing exposure and health disparities.

## **P01.0585. Developing Advanced PM2.5 Exposure Models in Lima, Peru**

Bryan Vu

*Bryan N. Vu<sup>1</sup>, Jianzhao Bi<sup>1</sup>, Odon Sánchez<sup>2</sup>, Gustavo F. Gonzales<sup>4</sup>, Kyle Steenland<sup>3</sup>, Yang Liu<sup>1</sup>*

*1. Environmental Health, Emory University, Decatur, GA, United States.*

*2. SENAMHI, Lima, Peru.*

*3. Emory University, Atlanta, GA, United States.*

*4. Universidad Peruana Cayetano Heredia, Lima, Peru.*

**Abstract:** Background: There is convincing evidence of adverse health effects induced by exposure to PM2.5 in the growing body of literature. Lima's topography and aging vehicular fleet results in severe air pollution with limited amounts of monitors to effectively quantify measurements for epidemiologic studies. Objectives: We propose to develop a high-performance satellite-driving exposure model to estimate daily PM2.5 concentrations at a 1 km spatial resolution in Lima, Peru from 2010 to 2016 using a combination of ground measurements, aerosol optical depth (AOD), meteorological fields, parameters from atmospheric chemical transport models, and land use variables. Methods: Parameters from the Weather Research and Forecasting model coupled with Chemistry (WRF-CHEM) and the European Centre for Medium-Range Weather Forecasts (ECMWF) were evaluated against ground monitoring stations from Weather Underground. A random forest model was used to gap-fill non-random missing satellite AOD data due to cloud cover to enhance spatial coverage and quality. Both a linear mixed effects model and a random forest model was used to fit AOD, WRF-CHEM, ECMWF, meteorological fields, and land use parameters against ground measurements from 16 monitoring stations with available data between 2014 to 2016. Both models were then used to estimate daily PM2.5 concentrations from 2010 to 2016. Results: The overall cross-validation (CV) R2 value and (RMSE) for the linear mixed effects model and random forest model was 0.58 (7.08 µg/m3) and 0.73 (5.66 µg/m3), respectively. The random forest model's robust ability to include more parameters outperformed the linear mixed effects model due to limited number of ground observations. Conclusions: Our models allow for construction of long-term historical daily PM2.5 levels to support fundamental and imperative epidemiological studies that will likely impact governmental policies on air quality in Lima, Peru.

## **P01.0590. Metabolic Syndrome and Its Mediation Effects of Fine Particulate Matter and Cardiovascular Disease**

Seulbi Lee

*1. Department of Medical Sciences, School of Medicine, Ewha Womans University, Seoul, Korea (the Republic of).*

*2. Department of Occupational and Environment Medicine, School of Medicine, Ewha Womans University, Seoul, Korea (the Republic of).*

*3. Department of Internal Medicine, College of Medicine, Ewha Womans University, Seoul, Korea (the Republic of).*

*4. Department of Preventive Medicine, College of Medicine, Ewha Womans University, Seoul, Korea (the Republic of).*

*5. Department of Statistics, Ewha Womans University, Seoul, Korea (the Republic of).*

**Abstract:** Background / Aims Considerable epidemiological evidence indicates particulate matter (PM) as a major risk factor for cardiovascular diseases (CVD). Also, Metabolic syndrome (MetS) is well known as an important risk factor for CVD and a few studies show epidemiological association between PM and MetS. However, a study on the effect of PM on CVD as a mediator of MetS is still scarce. Thus, we examined a mediation of the association between PM<sub>2.5</sub> and CVD by MetS. Methods / Results Participants of this study were 153,417 adults from the national health screening cohort provided by Korea National Health Insurance who had health examination from 2009 to 2015. MetS was defined by National Cholesterol Education Program the third Adult Treatment Panel and exposure to PM<sub>2.5</sub>, one-year average before CVD diagnostic, was assessed using a Community Multiscale Air Quality (CMAQ) model. To determine whether MetS is a mediator variable and to quantify the mediation effect, we conduct a counterfactual mediation analyses. The effect estimates (natural direct effect (NDE), natural indirect effect (NIE), and total effect) with 1- increase in one-year average PM<sub>2.5</sub> concentration and the percentage of the effect of mediator were calculated by logistic regression models. Also, 95% confidence interval (CI) were obtained from bootstrap method. Results from adjusted mediation analyses showed that the mediation was significant for the association between PM<sub>2.5</sub> and CVD (NIE: 1.001, 95% CI: 1.000 - 1.002). In addition, the percent of the total effect mediated by MetS was 13% (p-value: 0.04), in reference to a total adjusted odds ratio of 1.010 (95% CI: 1.005 - 1.013). Conclusion Our findings suggest that MetS might appear as a mediate on the association between PM<sub>2.5</sub> and CVD. These results highlight the need of a further study to clarify that exposure to one-year average PM<sub>2.5</sub> is associated with an increased risk of CVD mediated by MetS.

**P01.0600. Shale Gas Development, Natural Gas Flaring, and Pediatric Asthma Hospitalizations from 2000 to 2010 in Texas, U.S.A.**

Mary Willis

**Abstract:** Background: Current estimates indicate that 4.5 million Texans live within 1 mile of at least one shale gas development (SGD) site, yet the respiratory health effects of residing near this industry remain unclear. SGD activities are associated with decreased air quality, including known respiratory irritants. This study aims to quantify the association between specific SGD activities and pediatric asthma hospitalizations in Texas. Methods: We leverage a 32 million record database of Texas inpatient hospitalizations to examine the association between natural gas development and pediatric respiratory hospitalizations via multilevel logistic models. In contrast to previous studies, we implement a quasi-experimental design to account for pre-existing spatiotemporal asthma hospitalization trends. We then use a database of monthly production reports to assess the heterogeneity of impact from drilling-specific exposures including drilling type and gas flaring activities. Results: We find that any drilling yields odds ratios ranging from 1.13 (95% CI: 0.99, 1.30) to 1.86 (95% CI: 1.57, 2.22) depending on age groups. Our results demonstrate that conventional drilling (OR: 2.02; 95% CI: 1.69, 2.41) may yield a higher risk for pediatric asthma hospitalizations than unconventional drilling (OR: 1.63; 95% CI: 1.33, 2.00). Additionally, flaring activities are consistently associated with pediatric asthma hospitalizations across multiple age groups, ranging from 1.09 (95% CI: 0.96, 1.22) to 1.54 (95% CI: 1.32, 1.78). These results hold across multiple sensitivity analyses. Conclusion: Pediatric asthma hospitalizations are increased with SGD and are similarly affected by conventional and unconventional drilling. Flaring may be a potential pathway for this association.

## **P01.0620. Comparison of Prediction Algorithms for Modelling Air Pollution Surfaces**

Jules Kerckhoffs

*Jules Kerckhoffs<sup>1</sup>, Gerard Hoek<sup>1</sup>, Lutzen Portengen<sup>1</sup>, Roel Vermeulen<sup>1</sup>*

Abstract: Land use Regression (LUR) models for air pollutants have often been developed using linear regression techniques. More recently, other multivariable methods have been used varying from penalized regression techniques, to variable selection methods and machine learning algorithms. These algorithms may have statistical advantages over linear (stepwise) regression techniques as they may account better for correlated structures and more flexible relationships, for example. However, empirical comparisons between different multivariable algorithms have been limited. We compared several prediction algorithms that have been used previously to create spatial air pollution surfaces including stepwise (penalized) regressions, Deletion/Substitution/Addition (DSA) algorithm, general additive models (GAM), neural networks, and random forests. We used two training sets of ultrafine particle (UFP) data; one based on mobile measurements (8200 segments, 25 seconds monitoring per segment), the other based on short-term stationary measurements (368 sites, 3x30 minutes per site). We evaluated different modelling approaches by comparing predictions to external long-term average UFP concentrations. Models that allow flexible relationships and machine learning approaches tended to describe the training data better than multiple regression techniques, both for the mobile data and short-term data (best R<sup>2</sup> for machine learning is 0.29 vs R<sup>2</sup> range of 0.12-0.15 for multiple regression). However, high training model R<sup>2</sup> did not equate to high R<sup>2</sup> for the external long-term average concentrations, especially for machine learning algorithms trained on mobile measurements. Machine learning algorithms explained only 38-47% of external UFP concentrations whereas multivariable methods like linear stepwise regression, DSA and GAM were able to explain 56-62%. These results indicate that multivariable methods might be preferred methods for LUR-modeling based on theoretical and empirical grounds.

## **P01.0630. Estimation of Historic PM2.5 Concentrations Using the PM2.5-PM10 Ratio in Mexico City and Metropolitan Area**

Olivia Lingdao Chilian-Herrera

*Olivia Lingdao Chilian-Herrera<sup>1</sup>, José Luis Texcalac-Sangrador<sup>1</sup>, Martha M. Téllez-Rojo<sup>1</sup>, Stephen J. Rothenberg<sup>1</sup>, Ruy Lopez-Ridaura<sup>1</sup>, Marcela Tamayo y Ortiz<sup>1</sup>*

*1. National Institute of Public Health, Cuernavaca, Morelos, Mexico.*

**Abstract:** The Air Quality Monitoring System is the main source of particulate matter data in the Mexico City (MC) and Metropolitan Area (MA). The monitoring system's gradual development has produced variable coverage data throughout space and time, making difficult to use it for epidemiological studies. The WHO suggests to use the PM2.5-PM10 ratio (PMR) for PM2.5 estimation when only PM10 data is available. The aim was to estimate PM2.5 concentrations in the MC and MA using the PMR for 2003 to 2016, in order to increase space-time coverage data for epidemiological studies. The monitoring stations (MS) that measured simultaneously PM2.5 and PM10 were identified year by year. For each, the hourly PMR were estimated. Then, monthly and annual hourly PMR average were obtained. The hourly PM2.5 missing values in this MS were imputed by dividing the PM10 hourly data available between the annual hourly PMR average. In the MS that measured only PM10, PM2.5 monthly data was imputed using the monthly PMR average considering the location of the MS. The PM2.5 annual averages for each MS, for MC and MA were estimated. Pearson's correlation analysis and statistical significance tests were carried out between imputed and measured data. Procedures were done using R 3.4.1. and Stata 14. Higher annual hourly PMR average was observed in MC than in MA (54 vs 50%,  $p < 0.000$ ), and similar to the PMR suggested by the WHO (50%). PM2.5 was estimated for 101 MS which measured PM10 only, and for 5 MS which measured both. High concordance was observed between hourly data measured vs estimated for MS located in MC ( $R^2=0.83$ ) and in MA ( $R^2=0.73$ ). Most PM2.5 annual averages were no statistically different (data imputed included vs only measured data). Our results show that the PMR is an adequate method to robustly estimate space-time PM2.5 when only PM10 data is available. This study establishes a precedent for other urban areas where monitoring systems are growing and information of PM2.5 might not be available.

**P01.0640. Ozone and Emergency Department Visit for Asthma in the Seven Metropolitan Cities in Korea 2013-2015: A Case-Crossover Study**

Hyomi Kim

*Hyomi Kim<sup>1</sup>, Honghyok Kim<sup>1</sup>, Garam Byun<sup>1</sup>, Jong-Tae Lee<sup>1</sup>*

Abstract: Harmful effects of exposure to ground-level ozone on exacerbation of existing respiratory condition are supported by number of studies in various countries. The objective of this study was to determine the association between ozone and emergency department (ED) visits for asthma in seven metropolitan cities (Seoul, Busan, Incheon, Daegu, Gwangju, Daejeon, and Ulsan) in Korea. Emergency department visit records by asthma (ICD10: J45 or J46) were obtained from National Emergency Department Information System for the period of 2013 to 2015. Air pollutants and meteorological data were obtained from the National Institute of Environmental Research and the Meteorological Administration. A time-stratified case-crossover design was used to analyze relationship between ozone and ED visits by asthma. Pooled estimates across the seven cities were calculated using a fixed-effect model. In total, 21,259 ED visits were included. Mean ambient concentrations of ozone were ranged from 34.98ppb for Seoul to 41.84ppb for Gwangju. Estimated odds ratios (ORs) of ozone on ED visit by asthma with an increment of 10ppb were ranged from 1.061 (95%CI: 1.032-1.091) for Seoul to 1.323 (95%CI: 1.146-1.527) for Ulsan with 3-days lag period. The stronger associations were found in younger population (age<19) and estimated ORs were ranged from 1.088(1.099-1.173) in Incheon to 1.602(1.280-2.005). Estimated pooled OR estimates were 1.073(95%CI: 1.052-1.095) for the total population, 1.129(95%CI: 1.091-1.168) for younger population (age<19), 1.060(95%CI: 1.028-1.093) for adult population (19<=age<65), and 1.021(95%CI: 0.980-1.063) for elderly population (age>=65). This study results provide the evidence that short-term exposure to ozone increases ED visit by asthma, especially for younger population.

## **P01.0650. Modeling Transport of Windblown Soil Using HYSPLIT**

Naomi Riches

*Naomi O. Riches<sup>1</sup>*

*1. Family and Preventive Medicine, University of Utah, Salt Lake City, UT, United States.*

Abstract: Dust from soils originating in drylands of the Great Basin (located in California, Idaho, Nevada, and Utah), can travel thousands of kilometers from the source through atmospheric transport, carrying particulate matter (PM), pollutants, and allergens. Dust, specifically PM less than or equal to 2.5 $\mu$ m (PM<sub>2.5</sub>), negatively affects health, increasing the risk of respiratory disorders, cardiovascular disorders, and skin irritation. The Utah Department of Environmental Quality (DEQ) collects 24-hour samples within Salt Lake City, Utah of PM<sub>2.5</sub> every three to nine days, which are analyzed for elemental composition. This data will be coupled with the National Oceanic and Atmospheric Administration Air Resources Laboratory Hybrid Single-Particle Lagrangian Integrated Trajectory model (HYSPLIT), a modeling system that creates air parcel trajectories. HYSPLIT can model backwards trajectories to track past atmospheric movement. By combining these two resources, this study will be able to assign days into clusters by PM composition and assess the backwards trajectories of air parcels to determine the possible origins of the PM clusters. Malm et al., through the Interagency Monitoring of Protected Visual Environments study, identified the chemical composition of soil from "fine aerosol species." This was done by summing elements associated with soils with a correction factor for the oxides:  $[SOIL] = 2.20[Al] + 2.49[Si] + 1.63[Ca] + 2.42[Fe] + 1.94[Ti]$  The DEQ dataset was used to calculate [SOIL] using the elemental components. Days with high concentrations have been selected for analysis with HYSPLIT. We will utilize the backward trajectory models within HYSPLIT to assess where the samples containing [SOIL] originated. It is predicted that this method will identify areas with specific soil element fingerprints, which may help to designate resources for remediation if necessary as well as improving exposure assessment for public health studies.

## **P01.0660. Outdoor Air Pollution Exposure and Lung Cancer Incidence in Korea: A Nationwide Population-Based Cohort Study**

Garam Byun

*Garam Byun<sup>1</sup>, Hyomi Kim<sup>1</sup>, Honghyok Kim<sup>1</sup>, Yongsoo Choi<sup>2</sup>, Hyeonjin Song<sup>2</sup>, Sera Kim<sup>1</sup>, Sooyeon Kim<sup>1</sup>, Dahyun Baek<sup>1</sup>, Jong-Tae Lee<sup>2</sup>*

*1. BK21PLUS Program in 'Embodiment: Health-Society Interaction', Department of Public Health Sciences, Graduate School, Korea University, Seoul, Korea (the Republic of).*

*2. School of Health Policy and Management, College of Health Science, Korea University, Seoul, Korea (the Republic of).*

**Abstract:** Background/Aim: The International Agency for Research on Cancer (IARC) has concluded that exposure to outdoor air pollution causes lung cancer. Epidemiological studies on air pollution associated with lung cancer played a crucial role in their decision. However, most of the epidemiological evidence is limited to western countries. We aimed to investigate the association between long-term exposure to outdoor air pollutants and lung cancer incidence in Korea. Methods: National Sample Cohort data from 2002 to 2013 were obtained from National Health Insurance Service in Korea. The study population included a total of 28,090 subjects without pre-existing cancer at baseline. The district level annual-average concentration of particulate matter with a diameter  $\leq 10$   $\mu$ m (PM<sub>10</sub>), nitrogen dioxide (NO<sub>2</sub>), and ozone (O<sub>3</sub>) were assigned to each individual based on residential address which is updated annually. Cox-proportional hazard regression model was used to estimate the effects of long-term exposure to air pollution on the incidence of lung cancer. Different exposure matrices and lag years were considered. Results: During 263,178 person-years, 160 incident cases of lung cancer were observed. Increasing yearly mean exposure in 10 ppb O<sub>3</sub> was associated incident lung cancer (hazard ratio [HR]: 1.61, 95% CI: 1.07-2.41). The results showed no association between lung cancer and PM<sub>10</sub> (HR: 0.91, 95% CI: 0.72-1.15) or NO<sub>2</sub> (HR: 0.84, 95% CI: 0.63-1.10). Each follow-up period average exposure and average cumulative exposure to O<sub>3</sub> before censoring were also marginally associated with lung cancer. Conclusion: Lung cancer incidence was most strongly associated with long-term O<sub>3</sub> exposure in this Korean study. Further investigation is required to provide strong evidence, however, our study suggests that annual guideline for O<sub>3</sub> is recommended in Korea.

**P01.0670. Estimating Exposure to Ultrafine Particles in the Greater Montreal Area among Case-Control Study Subjects: Comparison of Classical Land Use Regression Model with a Model Based on Bayesian Principles.**

Shilpa Karumanchi

*Shilpa L. Karumanchi<sup>1</sup>, Jack Siemiatycki<sup>1</sup>, Lesley Richardson<sup>2</sup>, Marianne Hatzopoulou<sup>3</sup>*

*1. School of Public Health, University of Montreal, Montreal, QC, Canada.*

*2. Department of Population health, Centre de recherche du Centre hospitalier de l'Université de Montreal, Montreal, QC, Canada.*

*3. Civil Engineering, University of Toronto, Toronto, ON, Canada.*

**Abstract:** Background: Despite currently inconclusive results there is evidence accumulating that ultrafine particles (UFP), a major portion of the particulate matter of air pollution, may play a role in the development of lung cancer. Ultrafine particles (UFPs), the finest particulate matter in air, vary with space and time which is a challenge in estimating levels of exposure for individuals in health studies. Therefore, we aim to evaluate robustness of two statistical regression models in estimating the levels of ultrafine particles in atmospheric air for Greater Montreal area. Methods: A fixed site monitoring campaign was designed to measure the levels of ultrafine particles with a dense monitoring network of 250 sampling sites in the Greater Montreal Area. Ultrafine particles were measured for 20 minutes at each sampling site. In order to derive average annual levels, three repetitions were performed in winter and three in summer. However, high spatio-temporal variation of UFP makes it difficult to fit a regression model with high predictive value. In this analysis, we attempt to derive regression model for UFP within a Bayesian framework by considering the unobserved latent effect and euclidean distance between the sampling points. The proposed model attempts to capture the dependency of ultrafine particles between the sampling points that are close to each other. Results: The efficiency of conventional land use regression models in predicting UFP levels will be compared with spatiotemporal modelling in Bayesian framework with non-stationary covariance. Regression models will be developed using 90% of the sampling points. The remaining 10% will be used to evaluate the robustness of the models in estimating the UFP levels. Conclusions/Next steps: The best model for estimating the UFP levels will be used to derive an exposure surface for the Montreal area. This will be used to evaluate risk within a case-control study of lung cancer conducted in Montreal.

**P01.0690. Effects of Long-Term Exposure to Ambient Air Particles on Cause-Specific Mortality and Life Expectancy in Seoul, Korea**

Sera Kim

*Sera Kim<sup>1</sup>, Honghyok Kim<sup>1</sup>, Hyomi Kim<sup>1</sup>, Garam Byun<sup>1</sup>, Yongsoo Choi<sup>1</sup>, Hyeonjin Song<sup>1</sup>, Sooyeon Kim<sup>1</sup>, Jong-Tae Lee<sup>2</sup>*

*1. BK21PLUS Program in 'Embodiment: Health -Society Interaction', Department of Public Health Science, Graduate School, Korea University, Seoul, Korea (the Republic of).*

*2. Korea University, Seoul, Korea (the Republic of).*

**Abstract:** Background In South Korea, studies on the long-term effects of particulate matter with a diameter less than 10  $\mu\text{m}$  (PM10) are still limited. This study examined the effects of long-term exposure to PM10 on cause-specific mortality and life expectancy in Seoul, Korea. Methods Age-standardized mortality rates, life expectancy, and average annual levels of PM10 were computed for each 25 district in Seoul from 2004 to 2012. We used poisson regression to estimate the association between PM10 and cause-specific mortality and linear regression for life expectancy. The models were adjusted for area-level of socioeconomic status, smoking, health budget per capita, neighborhood safety, and green space using the Normalized Difference Vegetation Index (NDVI). Results Annual increase of 10  $\mu\text{g}/\text{m}^3$  in the concentration of PM10 was associated with increased all-cause, chronic lower respiratory disease, ischaemic heart disease, and hypertension mortality risk of 5.7% (95% CI: 4.4, 7.0%), 13.8% (95% CI: 9.2, 18.4%), 16.2% (95% CI: 12.0, 20.4%), 17.5% (95% CI: 8.7, 27%), respectively. Stratified analysis by sex showed that increase in mortality risk was higher for women. Effects of PM10 on cardiovascular mortality were higher in the districts with safer neighborhood environment. In the life expectancy analysis, annual 10  $\mu\text{g}/\text{m}^3$  increase in PM10 resulted in loss of life in 0.32 years (95% CI: -0.24, -0.40). Conclusions Long-term exposure to PM10 was associated with increased in cause-specific mortality and decreased life expectancy in Seoul, Korea.

**P01.0700. A Panel Study of Acute Cardiovascular Health Effects in Relation to Exposure to Traffic-Related Air Pollutants and Noise in Toronto, Canada**

Rita Biel

*Rita Biel<sup>1</sup>, Marianne Hatzopoulou<sup>2</sup>, Maryam Shekarrizfard<sup>2</sup>, Laura Minet<sup>2</sup>, Rick Liu<sup>2</sup>, Scott Weichenthal<sup>1</sup>*

- 2. Department of Civil Engineering, University of Toronto, Toronto, ON, Canada.*

**Abstract:** Introduction: Air pollution is a known risk factor for death from heart disease. Urban populations are exposed to air pollutants (APs) and varying levels of noise in high-traffic environments. Acute, physiologic responses of the cardiovascular system may be important mechanisms by which these stressors trigger cardiovascular events. Methods: In 2016, we carried out a panel study of APs and noise in 46 adults who were non-smokers with no prior cardiovascular morbidity in Toronto, Canada. Personal (PM<sub>0.1</sub>, BC) and regional (PM<sub>2.5</sub>, O<sub>3</sub>, NO<sub>2</sub>) measures of APs and noise were collected and oxidant capacity (Ox) was estimated from NO<sub>2</sub> and O<sub>3</sub>. We used linear mixed models with random subject intercepts to estimate associations between 8-hour average pollutant exposures and baseline-to-follow-up changes in endothelial function (RHI), blood pressure and heart rate, adjusted for temperature and 24-hour alcohol/caffeine intake. Results: Each IQR increase in regional PM<sub>2.5</sub> (5.5 µg/m<sup>3</sup>), O<sub>3</sub> (12.2 ppb) and Ox (7.4 ppb) exposure was associated with a decrease in RHI ( $\beta = -0.45$  95% CI -0.81- -0.09,  $\beta = -0.29$  95% CI -0.56- -0.02,  $\beta = -0.31$  95% CI -0.56- -0.06, respectively). Endothelial function worsened further among subjects with a BMI of  $\geq 25$  kg/m<sup>2</sup> with exposure to O<sub>3</sub> ( $\beta = -1.34$  95% CI -1.76- -0.92) and Ox ( $\beta = -1.26$  95% CI -1.71- -0.80). Each IQR increase in PM<sub>0.1</sub> (14,934 particles/cm<sup>3</sup>) was associated with a 2.5 beats/min higher heart rate among women (95% CI 0.74-4.27) and not men (p-interaction <0.05). No deleterious associations with continuous exposure to noise were found. BC exposure (1,163.8 ng/m<sup>3</sup>) was associated with an increase in heart rate among those exposed to noise levels above the median (67 dBA) ( $\beta = 2.61$ , 95% CI 0.02-5.19). Conclusion: Persons with BMI of  $\geq 25$  kg/m<sup>2</sup> were more susceptible to worsened endothelial function with exposure to O<sub>3</sub> and Ox, while women had increased heart rate with exposure to PM<sub>0.1</sub>. Higher levels of noise may impact associations of APs with heart rate.

## **P01.0710. Residential Proximity to Roadways and Placenta-Associated Stillbirth: A Case-Control Study**

Lindsey Butler

*Lindsey J. Butler<sup>1</sup>, Lisa Gallagher<sup>2</sup>, Michael Winter<sup>3</sup>, Patricia Fabian<sup>1</sup>, Amelia K. Wesselink<sup>2</sup>, Ann Aschengrau<sup>2</sup>*

*1. Environmental Health , Boston University School of Public Health, Boston, MA, United States.*

*2. Epidemiology , Boston University School of Public Health, Boston, MA, United States.*

*3. Biostatistics and Epidemiology Data Analytics Center, Boston University School of Public Health, Boston, MA, United States.*

Abstract: Previous studies suggest that risk of stillbirth is elevated by maternal exposure to air pollution. We conducted a retrospective case-control study of 1,097 women to examine the association between stillbirth related to placental abruption or placental insufficiency and maternal exposure to traffic related air pollution. We utilized distance to nearest roadway proximity metrics as a proxy for traffic-related air pollution exposure. No meaningful increase in the overall odds of placental-associated stillbirths was observed (adjusted OR: 1.1, 95% CI: 0.5-2.8). However, mothers living within 50 meters of a roadway had a 60% increased odds of experiencing a stillbirth related to placental abruption compared to mothers living greater than 200 meters away, This suggestive finding was imprecise due to the small case number in the highest exposure category (95% CI 0.6-4.0). Future studies of placental abruption with more precise exposure assessments are warranted.

## **P01.0720. Measuring Personal Environmental Exposures Using a Wearable Air Pollutant Monitor**

Elizabeth Lin

*Elizabeth Lin<sup>1</sup>, Sarah Esenther<sup>1</sup>, Fareeha Irfan<sup>1</sup>, Massimiliano Mascelloni<sup>1</sup>, Krystal J. Pollitt<sup>1</sup>*

*1. Environmental Health Sciences, University of Massachusetts, Amherst, MA, United States.*

**Abstract:** Traditional personal air pollutant monitoring systems include backpacks containing hand-held air monitors and filters/pumps which are worn for several days. Given the size, weight and cost of these sampling systems, use with vulnerable populations (i.e. pregnant women, infants) is not feasible. There has been limited development of analytical techniques to capture the cumulative exposure of an individual to multiple air pollutants. New exposure assessment tools are required to better study longitudinal environmental exposures. We have developed the Fresh Air wristband to profile personal organic air pollutant exposures using a non-selective passive sampling technique. Pollutants are collected onto a sorbent bar housed within a silicone wristband. The sorbent bar is coated with a thin-film polymer substrate which accumulates non-polar air pollutants with a log K<sub>ow</sub> ranging between 4 and 8. The wristband is worn by an individual for a multi-day period and then analysed using high resolution gas chromatography time-of-flight mass spectrometry with thermal desorption. With this personal exposure assessment tool, we can quantify the time-weighted averages of exposure to a panel of volatile and semi-volatile organic compounds during typical daily activities without impairing motion. We will present data on the functionality of the Fresh Air wristband as a non-selective passive air pollutant sampler. Application of this new personal exposure assessment tool in a cohort of 60 school-aged children residing in Springfield, MA will further be discussed. Improved assessment of exposure using the Fresh Air wristband across life stages (pregnancy, infancy, childhood) has the potential to produce a more comprehensive understanding of the air pollutants that mediate adverse health.

## **P01.0730. Household Air Pollution and Telomere Length in Rural Chinese Women Using Biomass Stoves**

Sabrina Li

*Sabrina Li<sup>1</sup>, Ming Yang<sup>2</sup>, Ellison Carter<sup>3</sup>, James J Schauer<sup>4</sup>, Xudong Yang<sup>5</sup>, Majid Ezzati<sup>6</sup>, Jill Baumgartner<sup>7</sup>*

**Abstract:** Background: Short telomeres are associated with chronic disease and early mortality. Urban and traffic pollution has been associated with telomere attrition in adults and children. The associations of household air pollution from biomass stoves and telomere length are unknown. Objectives: To investigate the associations between household air pollution and telomere length in adult women. Methods: We conducted a repeated-measure (one summer and two winter seasons) panel study of 137 rural Chinese women (mean age=55 y), measured their 48-h personal exposure to fine particulate matter (PM<sub>2.5</sub>) and black carbon (BC), and collected their oral DNA that was analyzed for relative telomere length (RTL). Non-linear associations were assessed using natural cubic splines (2-4 DF). Multivariate mixed models were used to examine the relationship between air pollution exposure and telomere length. Results: Air pollution exposures ranged from 13-945 µg/m<sup>3</sup> (arithmetic mean=141, SE: 11) for PM<sub>2.5</sub> and 0.1-139 µg/m<sup>3</sup> (mean=4.1, SE: 0.4) for BC. Spline models illustrated that the associations between air pollution and RTL were non-linear. A 1-ln (µg/m<sup>3</sup>) increase in air pollution was associated with lower RTL (PM<sub>2.5</sub> [-0.45, 95% CI: -0.88, -0.02, p=0.04], BC [-0.81, 95% CI: -1.21, -0.39, p<0.001]) after adjusting for age, waist circumference, ethnicity, secondhand smoke, sodium intake, day of the week, and time of day. Additionally adjusting for ambient temperature reduced the effect of air pollution by 23-62% (BC [-0.62, 95% CI: -1.09, -0.15, p=0.01]; PM<sub>2.5</sub> [-0.17, 95% CI: -0.72, 0.39], p=0.54), which may be due to more frequent biomass burning to heat homes when the outdoor temperature is colder. Conclusion: Household air pollution exposure is associated with shorter telomeres in rural Chinese women cooking with biomass fuel, with stronger associations for BC than PM<sub>2.5</sub> mass.

## **P01.0740. Assessment of Household Air Pollution Exposure and Associated Health Effects from Burning Firewood and Yak Dung on the Eastern Tibetan Plateau**

2. *Department of Environmental Sciences, Emory University, Atlanta, GA, United States.*

3. *College of Environmental Sciences and Engineering, Peking University, Beijing, China.*

**Abstract:** Background: Cooking and heating with solid fuels produces high levels of household air pollution (HAP) and is a substantial contributor to the disease burden. This study assesses the sources, magnitudes, and chemical compositions of HAP in traditional Eastern Tibetan Plateau households; examines the perturbation of urine metabolome in response to the HAP exposure; and explores how these correlate with cookstove use, fuel type, cooking behaviors, and residents' overall health. Methods: We measured 24-hour personal exposure to PM<sub>2.5</sub> (n = 46) and kitchen area black carbon (BC) concentrations (n = 8), using MicroPEM and microAeth, respectively. We also measured particle-bound polycyclic aromatic hydrocarbon (PAH) (n = 12) and metal concentrations (n = 11) during post-analysis of the MicroPEM filter. We conducted household surveys (n = 24) regarding demographics, cookstove usage, fuel type, cooking behavior, and lifestyles. In addition, we collected fasting urine (n = 46) and applied untargeted metabolite profiling to monitor metabolic features and assess associations with measured HAP exposures. These data will be analyzed with bioinformatics approaches-Manhattan plot and Mummichog pathway analysis. Results: Our results reaffirm that burning firewood and yak dung, result in high PM<sub>2.5</sub> and BC exposures. The geometric mean (95% CI) concentration was 92.2 (12.5, 682.4) µg/m<sup>3</sup> for PM<sub>2.5</sub> and the mean ± standard deviation (SD) concentration was 5.8 ± 5.5 µg/m<sup>3</sup> for BC, 474.3 ± 584.3 ng/m<sup>3</sup> for EPA standard suite of 16 PAHs, respectively. The mean ± SD of concentrations of twenty-five detected metal elements ranged from 0.9 ± 1.1 (Co) to 1585.1 ± 1621.5 ng/m<sup>3</sup> (Si). Our statistical analyses illustrate high concentrations of PM<sub>2.5</sub>, BC, most PAHs and metals are significantly associated with village characteristics and household fuel types. Conclusion: Results from this study provide useful information for understanding the HAP exposure and related health risks in Tibetan communities.

## **P01.0750. Report Back of NO<sub>2</sub> and PM<sub>2.5</sub> Concentrations from a Community Based In-Home Exposure Monitoring Study**

Claire Schollaert

Abstract: Exposure studies have been increasingly including report back of results to participants. This information can be used to decrease exposures, increase public understanding of science, and improve health. As part of the Center for Research on Environmental and Social Stressors in Housing across the Life Course (CRESSH), we reported back nitrogen dioxide (NO<sub>2</sub>) and particulate matter (PM<sub>2.5</sub>) results to participants of a home-based exposure monitoring study that took place over the course of a week in both a warm and cool season. Participants represented a diversity of racial/ethnic, socioeconomic, educational, and English language proficiency backgrounds. They also came from a diversity of housing situations (e.g., owner/tenant, single/multi-family, public/private). The report back process was developed in collaboration with GreenRoots, a community-based environmental justice organization, and Health Resources in Action, a national non-profit public health organization. The process included individualized reports and a community meeting, which established a space for participants to learn about general study results, ask questions, and discuss their interpretations. Results were presented using graphs reflecting daily averages of individual results for NO<sub>2</sub> and PM<sub>2.5</sub>, outdoor results of NO<sub>2</sub> and PM<sub>2.5</sub>, study-wide results for NO<sub>2</sub> and PM<sub>2.5</sub>, and national benchmarks and regulatory levels for comparative purposes. We also provided participants with information on the pollutants, strategies to reduce exposures, and projects to improve air quality in the community. Methods were developed and implemented in order to evaluate this report back process. Overall, this process was developed with a particular focus on the use of community-informed communication strategies, clear data visualization methods, and improving scientific literacy. We think that this strategy can be useful for other researchers who plan to report back results in future community-based exposure studies.

**P01.0760. Do Ambient Air Pollutant Concentrations during Pregnancy Impact Birth Weight among Women Living in Monroe County, New York? The Rochester Accountability Study**

Rui Li

*Rui Li<sup>1</sup>, Sally Thurston<sup>2</sup>, Philip Hopke<sup>1</sup>, Ann Dozier<sup>1</sup>, Kelly Thevenet-Morrison<sup>1</sup>, Edwin van Wijngaarden<sup>1</sup>, Daniel Croft<sup>3</sup>, Mauro Masiol<sup>1</sup>, Stefania Squizzato<sup>1</sup>, David Rich<sup>1</sup>*

Abstract: Increased ambient air pollutant concentrations during pregnancy have been associated with reduced birth weight, but the etiologically-relevant time window during pregnancy is unclear. Therefore, we studied the association between gestational month ambient air pollutant concentrations and birth weight in Monroe County, NY (2005-2016). We also examined whether associations differed BEFORE implementation of several air quality policies (2005-2007), compared to DURING (2008-2013) and AFTER implementation (2014-2016). We used measurement of fine particles (PM<sub>2.5</sub>), black carbon (BC), ultrafine particles (UFP; <100nm), accumulation mode particles (AMP; 100-500nm), sulfur dioxide (SO<sub>2</sub>), and ozone (O<sub>3</sub>) in Rochester, NY (2005-2016) and birth certificate data for 76,500 singleton term births (37-42 gestational weeks at delivery) born to Monroe County residents. For each pollutant, we separately regressed birth weight against the mean concentration in each gestational month and the last 31 days of pregnancy (10 models). We then explored effect modification by PERIOD, season, infant gender, maternal employment, and pregnancy complications. Overall, there were no clear patterns of birth weight change associated with increased pollutant concentrations across gestational months. However, increased and decreased birth weights were associated with interquartile range increases in black carbon in the 1st gestational month (13.4g increase; 95% CI=3.4, 23.4), UFP in the 6th month (7.5g decrease; 95% CI=-14.5, -0.4), O<sub>3</sub> in the 1st month (15.8g decrease; 95% CI=-31.5, -0.1) and O<sub>3</sub> in the 6th month (17.2g increase; 95% CI=3.1, 31.4). There were also no patterns of effect modification by PERIOD, infant gender, maternal employment, pregnancy complications, or season. However, among Hispanic women only, increases in all pollutants, except O<sub>3</sub>, in multiple gestational months were associated with decreased birth weight. Further work is needed to understand these differences by ethnicity.

**P01.0770. The Effects of Melatonin on the Relationship between Air Pollution Levels and Biomarkers of Oxidative Stress and Platelet Activation in Healthy Young Adults**

Abstract: Urinary free malondialdehyde (MDA) and 8-hydroxy-2'-deoxyguanosine (8-OHdG) as biomarkers of oxidative stress as well as soluble P-selectin as a biomarker of platelet activation have been associated with air pollution exposure. However, the results have not been consistent across studies. We hypothesize that this inconsistency might be due to modification of circulating melatonin, a free radical scavenger and a key factor in the DNA damage repair system, on MDA and 8-OHdG responses to reactive oxygen species induced by air pollution exposure. Melatonin also regulates PPAR $\gamma$ /FUNDC1/ mitophagy pathways, hence affecting P-selectin level. We conducted a longitudinal study involving 70 healthy young adults living on a hospital campus in Shanghai. Indoor and outdoor PM<sub>2.5</sub>, O<sub>3</sub>, and NO<sub>2</sub> were monitored throughout the study and combined with time activity pattern to estimate personal air pollution exposure. The results show that a 10% increase of urinary 6-sulfatoxymelatonin (aMT<sub>6s</sub>, a major metabolite of melatonin and highly correlated with circulating melatonin) was associated with a significant increase in urinary 8-OHdG by 2.4% [95% CI: 1.4%, 3.4%] and a significant decrease in urinary free MDA and soluble P-selectin by -1.5% [-2.4%, -0.6%] and -1.0% [-1.9%, -0.1%], respectively. Compared to unadjusted models (specified in parenthesis), models with urinary aMT<sub>6s</sub> as an effect modifier showed that 10  $\mu$ g/m<sup>3</sup> in PM<sub>2.5</sub> 12h personal exposure was associated with a change in urinary 8-OHdG by 11.0% [-2.4%, 24.3%] (unadjusted: -3.8% [-7.4%, -0.2%]), a change in urinary free MDA by 14.0% [2.4%, 25.7%] (unadjusted: -0.3% [-3.4%, 2.8%]), and 10  $\mu$ g/m<sup>3</sup> increase in NO<sub>2</sub> 12h personal exposure was associated with a change in P-selectin by 5.4% [-10.2%, 21.0%] (unadjusted: -5.3% [-9.5%, -1.1%]). Similar mediation effects were also observed for O<sub>3</sub>. These findings support the role of melatonin as a mediator for oxidative stress and platelet activation introduced by air pollution exposure.

## **P01.0780. Air Pollution and Metabolomics in Maternal Serum**

Qi Yan

*2. Emory University, Atlanta, GA, United States.*

**Abstract:** Background: Studies have shown that maternal exposed to air pollution can increase the risk of a variety of neurodevelopmental disorders. However, air pollution cannot be considered a well-established risk factor, partially due to a lack of valid exposure assessment methodology. Assessing environmental metabolomic profiles using high-resolution metabolomics (HRM) is a novel tool to investigate air pollution exposure history and related biological mechanism. Objectives: The aim of this study is to comprehensively profile metabolomics in the blood of women in mid-pregnancy and identify perturbations in metabolites and metabolic pathways associated with air pollution exposure by using HRM. Methods: We retrieved stored maternal serum samples from the mid-pregnancy alpha-fetoprotein testing program in California for a largely immigrant Hispanic community of women living in the Central Valley of California, a region with high particulate air pollution exposures. We developed measures of air pollution exposure at the mothers birth address. By using HRM, we identified significant metabolites and metabolic pathways within 99 exposed mothers and 62 unexposed mothers. Statistical methods include univariates analysis, multivariates analysis, and pathway enrichment analysis. Results: A set of 3917 metabolic features resulting from HRM were used for discriminant analysis and pathway analysis. We have identified 25 metabolites which can properly classify the air pollution exposure status with over 80% accuracy. Pathway analysis showed that air pollution exposure associated with leukotriene metabolism, amino acid metabolism, and pyrimidine and purine metabolism pathways. Conclusions: We found that maternal exposed to air pollution during pregnancy could potentially affect inflammation and oxidative stress-related metabolism, which may then contribute to the development of neurodevelopmental disorders in the offspring.

## **P01.0790. Standardizing Methods for Acellular Measurement of Oxidative Potential**

Alison Traub

*Alison Traub<sup>1</sup>, Cheol-Heon Jeong<sup>1</sup>, Cuilian Fang<sup>1</sup>, Maryam Shekarrizfard<sup>2</sup>, Hongyu You<sup>3</sup>, Marianne Hatzopoulou<sup>2</sup>, Scott Weichenthal<sup>4</sup>, Greg Evans<sup>1</sup>*

**Abstract:** Exposure to air pollution is associated with a broad suite of adverse health effects. Oxidative potential (OP) - the ability of pollutants to cause oxidative stress, measured per unit concentration - has emerged as a promising, biologically relevant metric for assessing risk associated with atmospheric pollutants. Notably, acellular measurements of OP, when applied to airborne particulate matter (PM), have been shown to be associated with cellular inflammatory response, cause-specific mortality, and other adverse health outcomes. Further, acellular in vitro methods are well suited for analyzing the large numbers of samples required to produce exposure data to support epidemiology studies. A standardized methodology was developed and applied to stream-line the most common acellular OP assays: The ascorbate, glutathione, and dithiothreitol assays. The assays were standardized to improve their reproducibility through strategic incorporation of blanks, calibration solutions and positive controls. This improved methodology was applied to 350 PM<sub>2.5</sub> samples collected from sites across Toronto and Canada. The standardized method has substantially improved assay reproducibility: depletion of ascorbate in blanks (no added PM) and a positive control (2.5  $\mu\text{M}$  Cu<sup>2+</sup>) varied by less than 4% and 6% respectively across multiple analyses completed with two spectrophotometers over a three-month period. Further, the coefficient of variance for the analysis of ascorbate depletion across replicates of any single PM sample was typically within 4%. Similarly, coefficients of variance for the analysis of glutathione and dithiothreitol depletion rates were consistently within 15%. Most importantly, failed assays could be quickly identified. As OP analysis becomes more widespread, application of a standardized analysis approach will become essential to increase inter-study comparability of OP measurements, and enhance the feasibility of collaborative, large-scale studies of OP.

## **P01.0800. Effect of Confounding, Effect Modification, and Exposure Measures on the Association of Long-Term Ozone Exposure and Cause-Specific Mortality**

Ki-Do Eum

*2. Northeastern University, Boston, MA, United States.*

**Abstract:** Introduction: Associations between long-term ozone (O<sub>3</sub>) exposure and cause-specific mortality have been demonstrated, although with varying exposure metrics and confounders. Methods: We assessed the association of warm season (April-September) averages of 1-hour daily maximum O<sub>3</sub> and cause-specific mortality for 22.2 million Medicare beneficiaries between 2000-2008. We modeled the national and regional associations between O<sub>3</sub> and rate of mortality using age, gender, and race stratified log-linear regression models. We examined confounding by including ecologic and neighborhood-level behavioral covariates and PM<sub>2.5</sub> estimated using spatio-temporal models. We also performed sensitivity analyses using exposure assessed as the warm season averages of daily 8-hour maximum and 24-hour average concentrations. We fit a log-linear model with a restricted cubic spline of O<sub>3</sub> to estimate the shape of the dose-response relationship between ozone and cause-specific mortality and examined effect modification of these associations by age, gender and race. Results: Our findings show that 1-hour maximum O<sub>3</sub> is significantly associated with an increased rate of death for all-cause (1.013 per 10 ppb increase; 95%CI: 1.012, 1.014), respiratory (1.036; 95%CI: 1.032, 1.039), cardiovascular (1.027; 95%CI: 1.025, 1.028) and lung cancer (1.016; 95%CI: 1.011, 1.020) mortality, but not for cancer mortality. Associations were generally strongest in the northeast US for all causes as compared to other US regions. Risk ratios were robust to adjustment for ecologic covariates, behavioral covariates and to PM<sub>2.5</sub>. Results remained significant but were attenuated when 8-hour daily maximum and 24-hour average measures of O<sub>3</sub> were used as the exposure measure, although 24-h averaged O<sub>3</sub> was associated with decreased all cause and cardiovascular mortality. Conclusions: Long-term exposure to O<sub>3</sub> was associated with increased mortality due to all-cause, respiratory, cardiovascular and lung cancer mortality.

**P01.0810. Association between Long-Term Exposure to Fine Particulate Matter Air Pollution and Mortality in a South Korean National Cohort**

Soo Lee

*2. Graduate School of Cancer Science and Policy, National Cancer Center, Goyang, Korea (the Republic of).*

**Abstract:** Previous cohort studies in Europe and North America have reported the relationship between long-term exposure to fine particulate matter air pollution and human health. However, there have been few studies in other areas because of the lack of nationwide PM<sub>2.5</sub> regulatory air quality monitoring data. This study examined the association between long-term exposure to PM<sub>2.5</sub> and mortality in a South Korean national cohort. We included 275,337 of 20-65 years at baseline, who had survived and underwent health screening for 2002-2006 with follow-up data through 2013 from the National Health Insurance Service-National Sample Cohort. Individual exposures to PM<sub>2.5</sub> were calculated as 5-year averages of district-specific annual average predictions of PM<sub>2.5</sub> at annually-updated residential addresses for 2002-2006. PM<sub>2.5</sub> predictions in 250 districts were estimated by using predicted district-specific annual means of PM<sub>10</sub> multiplied by annual ratios of PM<sub>2.5</sub> to PM<sub>10</sub>. We used Cox proportional hazards models to estimate hazard ratios (HRs) and their 95% confidence intervals (CIs) of non-accidental (The International Classification of Diseases, 10th revision: A00-R99), cardiovascular disease (I00-I99), and respiratory disease (J00-J99) mortality per 10 micrograms per cubic meter increase in PM<sub>2.5</sub>. In the models, we adjusted for individual covariates such as income, type of health insurance, smoking status and district-level demographic and socioeconomic variables. We did not find associations between PM<sub>2.5</sub> and all mortality with statistically insignificant HRs. HR for respiratory mortality was higher than for cardiovascular mortality (HR: 1.48 [95% CI: 0.87, 2.51]; 0.97 [0.76, 1.25] for respiratory and cardiovascular disease mortality, respectively). Our study do not provide evidence for associations between long-term PM<sub>2.5</sub> exposure and mortality. Future studies should investigate our findings of no associations by including additional confounders and/or subgroup analysis.

## **P01.0820. Data Needs for Measuring and Modelling Personal Exposure to Air Pollution: How Much Is Enough?**

Juan Orjuela

*Juan P. Orjuela<sup>1</sup>, Michelle Laeremans<sup>2</sup>, Ione Avila-Palencia<sup>3</sup>, Glòria Carrasco-Turigas<sup>3</sup>, Evi Dons<sup>2</sup>, Luc Int Panis<sup>2</sup>, Mark Nieuwenhuijsen<sup>3</sup>, Audrey de Nazelle<sup>1</sup>*

- 1. Centre for Environmental Policy (CEP), Imperial College London, London, United Kingdom.*
- 2. Flemish Institute for Technological Research (VITO), Mol, Belgium.*
- 3. ISGlobal, Barcelona, Spain.*

**Abstract:** Introduction: Impacts of daily activities and physical activity (PA) levels on personal exposure to air pollution are consistently understudied in epidemiological studies. Some researchers have included people's variable daily locations in their analysis and only a handful of publications mention the importance of breathing rates. Ignoring variables such as microenvironmental factors and inhalation rates introduces bias and uncertainty but estimating them for large populations can be challenging and expensive. This study presents a method for estimating inhaled doses based on limited collected data. Method: As part of the EU-funded PASTA project, we collected black carbon (BC) exposure concentrations, geolocation, and PA data from a free-living population (122 participants) in three European cities between 2015/16. Daily inhaled doses and average concentrations were analyzed as a function of travel mode, season, time of day and geolocation. Furthermore, half of the BC and PA data collected was used to develop regression models to estimate personal exposure concentrations and inhaled doses using one of three different kinds of input data: online survey data, a combination of GPS and survey data, and a combination of survey data and activity diaries. To assess the value of information, the results of each model were compared to calculated values using the remaining half of the data for validation. Results: Differences in personal exposures and inhaled doses for different travel mode users were statistically significant with, for example, cyclists inhaling 22% more on average than motorists. Inhaled doses were shown to be adequately modelled through a combination of surveys and limited monitoring data. The additional effort of collecting GPS data is not justified in some cases. Conclusion: Limited data collected from personal monitors can be used to develop statistical models that estimate inhaled doses of air pollution of larger cohorts.

**Abstract:** Background: Changes in vascular function may play a role in the association between short-term exposures to particulate matter (PM) air pollution and cardiovascular events. However, few studies have evaluated whether arterial stiffness increases in response to acute PM exposures, particularly among individuals who are at higher risk for developing cardiovascular disease (CVD), such as children and young adults with type 1 diabetes (T1D). Objectives: We examined the relationship of short-term exposures to PM<sub>2.5</sub>, elemental carbon (EC) and Atmospheric Dispersion Modeling System (ADMS)-Roads traffic-related PM near roadways with pulse wave velocity (PWV), a measure of arterial stiffness, using data from the SEARCH for Diabetes in Youth Study (SEARCH). Methods: PWV, lifestyle and demographic data were collected at a SEARCH study visit. Pollutant exposures were estimated using spatio-temporal models and assigned to the residential address of each participant for 7 days prior to the study visit. We estimated associations between different exposure windows (daily and weekly averages) of each air pollutant and PWV using separate generalized linear models adjusted for demographic and lifestyle variables. Results: Approximately 44% of the 352 participants were female and 86% were white, with a mean age of 14.6 years. In fully adjusted models, comparing the 25th and 75th percentiles of PM<sub>2.5</sub> mass exposures on lag day 0 resulted in a 5.8% higher PWV (95% CI: 0.7%, 11.2%). No other significant associations were observed. Conclusions: In this population of youth with T1D, PWV was associated with PM<sub>2.5</sub> mass on lag day 0. However, no associations were observed for acute exposures to other traffic-related air pollutants. In further analysis, we will examine the relationships of PM<sub>2.5</sub> mass and traffic-related air pollutant exposures with additional measures of cardiovascular structure and function.

## **P01.0850. Short-Term Exposure to PM2.5 Associated with Cardiovascular and Cerebrovascular Mortality in Mexico City from 2004-2013**

Iván Gutiérrez-Avila

*4. Department of Environmental Medicine and Public Health, Icahn School of Medicine at Mount Sinai, New York City, NY, United States.*

**Abstract:** Background. The association between short-term exposure to particles with aerodynamic diameter  $\leq 2.5 \mu\text{g}$  (PM2.5) and daily mortality has been extensively described in cities of developed countries. Only limited evidence exists on short-term exposure to PM2.5 associated with specific causes of cardiovascular and cerebrovascular mortality in cities of developing countries. Methods. We obtained daily mortality records for Mexico City for 2004-2013 for all cardiovascular and cerebrovascular causes, ischemic heart disease, hemorrhagic and ischemic stroke in people  $\geq 25$  and  $\geq 65$  years old. Daily exposure to PM2.5 was assessed with estimates from a new hybrid spatiotemporal model using satellite measurements of Aerosol Optical Depth (AOD-PM2.5) and compared to PM2.5 measurements from ground-level monitoring stations with missing data estimated with Generalized Additive Models (GAM-PM2.5). We fitted Poisson regression models with distributed lags to evaluate the association between short-term exposure to AOD-PM2.5 and GAM-PM2.5 with daily cardiovascular and cerebrovascular mortality. Results. We found a 1.22% (95% CI: 0.17-2.28) increase in cardiovascular mortality and 3.43% (95% CI: 0.10-6.28) increase in cerebrovascular mortality per 10- $\mu\text{g}/\text{m}^3$  increase in AOD-PM2.5 for the cumulative exposure over two days (lag0-1). The association between AOD-PM2.5 with hemorrhagic stroke was 4.01% (CI 95%: 0.37-7.77) for same day exposure (lag0). People  $\geq 65$  years old showed the largest associations for cardiovascular mortality (2.29% increase, 95% CI:0.98-3.63) and cerebrovascular mortality (4.70% increase, 95% CI:0.39-9.19) for the cumulative exposure over six days (lag0-6). Associations were slightly smaller using GAM-PM2.5. Conclusions. Our results suggest that PM2.5 pollution should be seen as a modifiable risk factor in the prevention of acute cardiovascular and cerebrovascular events in Mexico City.

## **P01.0860. Assessment of Particle Oxidative Potential as an Air Pollution Exposure Metric: A Systematic Review**

Susannah Ripley

*Susannah Ripley<sup>1</sup>, Scott Weichenthal<sup>1</sup>*

*1. Epidemiology, Biostatistics and Occupational Health, McGill University, Outremont, QC, Canada.*

**Abstract:** Ambient particulate air pollution is linked to numerous acute and chronic health outcomes. The standard approach to measuring particulate exposure has been to estimate particle mass concentration. New measures account for oxidative potential, the ability of particles to cause oxidative stress in the body. There has been no systematic comparison of particulate air pollution exposure assessment methods between those that incorporate oxidative potential and those that do not. The aim of this review is to determine if associations between particulate air pollution exposure and health outcomes are stronger when oxidative potential is used as the exposure metric, in comparison to particle mass concentration. The databases Medline and Embase were searched from inception to 28 March 2018 for studies that reported an association between particulate air pollution exposure and a health outcome in a human population, and in which exposure was measured by both particle mass concentration and oxidative potential. Study quality was assessed using a US National Toxicology Program instrument. We identified 18 publications meeting the selection criteria. The most common oxidative potential assay was antioxidant depletion in synthetic respiratory tract lining fluid, used in 12 articles. The rate of consumption of dithiothreitol was also frequently used as an oxidative potential assay and appeared in 5 studies. The dithiothreitol assay most consistently produced stronger effect estimates, as 10/14 endpoints showed higher point estimates of associations compared to particle mass concentration estimates. Other assays showed mixed results. To date there is no consistent evidence that oxidative potential is more strongly associated with health outcomes than particle mass concentrations; however, these assays do have the advantage of not treating all particles as equally harmful and further work should explore which specific assays are most relevant to evaluating air pollution health risks.

## **P01.0870. Acute Changes in Augmentation Index and Pulse Wave Velocity Following Controlled Exposures to Cookstove Air Pollution in the Subclinical Tests of Volunteers Exposed to Smoke (Stoves) Study**

Abstract: Household air pollution from solid fuel cookstoves is a leading cause of morbidity and mortality globally. Nearly half of the estimated 2.5 million premature deaths from cookstoves in 2016 were due to cardiovascular disease. There have been attempts to design improved cookstoves, yet it is unclear if they meaningfully improve health. The aim of this study was to assess the acute effects of pollution from multiple stoves on cardiovascular outcomes using a crossover controlled exposure design. Forty-eight young, healthy participants were assigned to six, two-hour exposure treatments: emissions from five cookstoves with a target concentration for fine particulate matter (liquid petroleum gas: 10  $\mu\text{g}/\text{m}^3$ ; semi-gasifier: 35; fan rocket: 100; rocket elbow: 250; open fire: 500), and filtered air control (0  $\mu\text{g}/\text{m}^3$ ). Augmentation index (AIx) and pulse wave velocity (PWV) were assessed before and three timepoints (zero, three, and 24 hours) after each treatment. Linear mixed models were used to assess differences in AIx and PWV for each treatment compared to filtered air. Preliminary results suggest elevated levels of AIx three hours after fan rocket (1.7 percentage points; 95% confidence interval [CI]: -1.5, 4.9) and open fire treatments (2.4 percentage points; 95% CI: -0.8, 5.6) compared to filtered air. PWV levels were higher 24 hours after all treatments compared to filtered air. For example, the difference between semi-gasifier and filtered air was 0.16 meters/second (m/s) (95% CI: -0.007, 0.33). No other differences were observed except higher PWV three hours after semi-gasifier treatment (0.18 m/s; 95% CI: 0.005, 0.36). AIx and PWV are established indicators of future cardiovascular risk. Our results suggest both may increase in healthy adults after short-term exposure to cookstove pollution. Along with complementary results from field studies, our results may provide insight into benefits of new and current cookstove technologies. This abstract does not represent EPA policy.

**P01.0880. Association between PM2.5 and Systemic Autoimmune Rheumatic Diseases: A Cohort Study in Taiwan from 2001 to 2011**

Chi-Min Wang

*Chi-Min Wang<sup>1</sup>, Chau-Ren Jung<sup>1</sup>, Wei-Ting Chen<sup>2</sup>, Bing-Fang Hwang<sup>1</sup>*

*1. Department of Occupational Safety and Health, China Medical University, Taichung, Hsueh-Shih Road,, Taiwan.*

*2. Department of Atmospheric Sciences, National Taiwan University, Taipei, Taiwan.*

**Abstract:** Background: Systemic autoimmune rheumatic diseases (SARDs) are a group of diseases with abnormally inflammatory reactions, such as dermatomyositis (DM), polymyositis (PM), systemic sclerosis (SSc). The pathogenesis of systemic autoimmune diseases is still unclear. Only a few studies accessed the relation between exposure to air pollution and systemic inflammation and provide inconsistent results. We conducted a prospective cohort study to investigate the associations between fine particulate matter (PM2.5) and SARDs, namely DM, PM, SSc, in Taiwan. Methods: The study population were obtained from Taiwan National Health Insurance Research Database (NHIRD) and followed up from 2001 to 2011. All participants were followed end when diagnosis of SARDs (DM, PM, SSc), or death, or end of the study. We developed a model integrated 3-km AOD with meteorological parameters and land use data to predict daily PM2.5 concentrations across Taiwan. We performed a time dependent Cox models to assess the effects of yearly average PM2.5 on SARDs (DM, PM, SSc). The results were reported as hazard ratios (HRs) with 95% confidence interval (CI). Results: A total of 3119 DM cases, 3259 PM cases, and 2824 SSc cases were identified during the study period. The mean age of DM, PM, and SSc cases were 54.4±18.7, 53.8±16.8, and 49.9±15.9 years, respectively. After adjusting for sex, age, and socioeconomic status, the results showed that exposure to an Interquartile range (IQR) increase in PM2.5 level (14.29 µg/m<sup>3</sup>) were associated with an approximately 48% increased risk of DM (95% CI 1.39--1.59) and a 23% increased risk of PM (95% CI 1.16-1.32). We did not observe significant associations between PM2.5 and SSc. Conclusions: Our study suggests that exposure to PM2.5 may increase the risk of DM and PM. The future studies would be needed to confirm these associations, and explore potential toxicants on SARDs other than PM2.5.

## **P01.0890. Effect of Long-Term Exposure to Ambient Fine Particulate Matter on Renal Function in the PURSE-HIS Cohort**

Zoe Petropoulos

*Zoe Petropoulos<sup>1</sup>, Kevin J. Lane<sup>1</sup>, Sadagopan Thanikachalam<sup>2</sup>, Mohan Thanikachalam<sup>3</sup>*

*1. Environmental Health, Boston University School of Public Health, Boston, MA, United States.*

*2. Cardiac Care Centre, Sri Ramachandra University, Chennai, India.*

*3. Public Health and Community Medicine, Tufts University School of Medicine, Boston, MA, United States.*

**Abstract:** **BACKGROUND:** Studies on the association between fine particulate matter (PM<sub>2.5</sub>) and kidney disease are limited. We investigated the association between PM<sub>2.5</sub> exposure and renal function in the Urban, Rural, Semi-urban Endovascular disease and Holistic Intervention Study (PURSE-HIS) cohort in India. **METHODS:** The study included 8,080 randomly selected subjects (mean age: 42 years; 58% female). We used PM<sub>2.5</sub> estimates developed for Global Burden of Disease as exposure at residence. Fasting blood samples were used to assess serum creatinine and the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation was used to derive the estimated glomerular filtration rate (eGFR). Generalized linear regression models, with stratification by diabetes and hypertension status, were used to test the association between PM<sub>2.5</sub> and urinary albumin. Logistic regression was used to estimate the odds of eGFR < 60 ml/min/1.73 m<sup>2</sup>, a cutoff for chronic kidney disease (CKD). All models were adjusted for age, sex, waist circumference, and smoking status. **RESULTS:** In linear regression models, an interquartile range (IQR) increase in PM<sub>2.5</sub> (3.0 µg/m<sup>3</sup>) was associated with an increase in urinary albumin (1.4 mg/L [95% CI: -1.5, 4.4]). A similar association was found in non-diabetics (1.2 mg/L [95% CI: -0.9, 3.3]), but not among diabetics. Stratification by hypertension did not significantly modify the relationship. An IQR increase in PM<sub>2.5</sub> was associated with higher odds of CKD (OR: 1.14 [95% CI: 1.06, 1.23]). **CONCLUSIONS:** Exposure to PM<sub>2.5</sub> was significantly associated with CKD. PM<sub>2.5</sub> was associated with urinary albumin in non-diabetics, an indication that PM<sub>2.5</sub> may have an effect on the kidney microvasculature. Longitudinal follow up is necessary to better understand the relationship between PM<sub>2.5</sub> exposure and kidney injury and dysfunction.

## **P01.0900. Health Benefits of Ozone Warning System in Three Major Cities of South Korea: A Regression Discontinuity Design**

Honghyok Kim

*Honghyok Kim<sup>1</sup>, Garam Byun<sup>1</sup>, Hyomi Kim<sup>1</sup>, Yongsoo Choi<sup>1</sup>, Jong-Tae Lee<sup>2</sup>*

*1. BK21PLUS Program in 'Embodiment: Health -Society Interaction', Department of Public Health Science, Graduate School, Korea University, Seoul, Korea (the Republic of).*

*2. School of Health Policy and Management, College of Health Science, Korea University, Seoul, Korea (the Republic of).*

**Abstract:** Background: Ozone warning system is operating in cities of South Korea. The first stage warning is issued if 1-hour average of ground-level ozone exceeds 120 ppb. Using a case-crossover design combined with a regression discontinuity design (RDD), this study assessed whether the warning system provides health benefit Methods: Since ozone warnings are alerted independently over zones within a city and individuals were assumed to be exposed to ground-level ozone differently (e.g. due to outdoor activities), a fuzzy RDD was applied to estimate the causal effect of the first stage warning on hospital visits and hospitalizations for allergic rhinitis (J30), asthma (J45), pneumonia (J12-18) and chronic lower respiratory disease (J40-44) in three major cities of South Korea (Seoul, Busan, and Daegu) during the period of 2008-2013. Based on a time-stratified case-crossover design, we applied a conditional Poisson regression with over-dispersion. Temperature, relative humidity, holiday and influenza epidemic were adjusted for. Lag effects up to previous 5 days of exposure were considered. Results: A total of 30, 28, and 21 days exceeded 120 ppb of 1-hour maximum of ground-level ozone in Seoul, Busan, Daegu respectively. The first stage warning led to reductions (intent-to-treat effects) in hospital visits and hospitalizations for allergic rhinitis, asthma, pneumonia and chronic lower respiratory diseases. The decrements differed by the health outcomes and the cities, and ranged from 6.0% (95% CI: -0.6 to -11.1) in hospital visit for asthma in Seoul to 23.4% (95% CI: -0.18 to 41.5) in hospitalization for asthma in Busan. We also found evidence on some harvesting effects (i.e. increases of hospital visits and hospitalizations following the initial reductions by the warning). Conclusion: Ozone warning system in South Korea reduces hospital visits and hospitalizations for respiratory diseases.

## **P01.0910. Childhood Incident Obesity and Traffic-Related Air Pollution among School-Aged Children**

Hua Hao

*Hua Hao<sup>1</sup>, Zhanghua Chen<sup>1</sup>, Rima Habre<sup>1</sup>, Frank Gilliland<sup>1</sup>*

*1. Keck School of Medicine, University of Southern California, Los Angeles, CA, United States.*

**Abstract:** Background: Recent studies suggest that traffic-related air pollution exposure may play a significant role in childhood obesity epidemic. Objectives: The present study was conducted to examine the longitudinal association between traffic-related and ambient air pollution exposures and childhood overweight or obesity (OWOB) onset. Methods: We recruited 3,075 normal weight kindergarten or first grade children from participants in the prospective cohort of southern California Children's Health Study (CHS). Individual covariates were reported annually through questionnaires and OWOB status (n=768) were categorized based on body mass index (BMI) and referred to CDC growth chart. Near-roadway pollution (NRP) was represented by nitrogen oxides (NO<sub>x</sub>), and was estimated based on residential addresses using a line source dispersion model accounting for traffic-volume, proximity, and meteorology. Ambient air pollutants including ozone, nitrogen dioxide, and particulate matter were measured at central site monitors in 13 study communities. We used proportional hazard model to analyze the association of annual averaged NRP and ambient air pollution exposures during one-year before baseline visit (2002-2003) with the risk of developing OWOB during an 8-year study follow-up. Results: Two standard deviation (5.41 ppb) increase of NRT of non-freeway NO<sub>x</sub> during one-year before baseline visit was associated with 12% increased risk of developing OWOB [HR=1.12, 95% CI = (1.01, 1.25)] during follow-up. The association was stronger among boys [HR=1.13, 95%CI= (1.01, 1.28)] compared to girls [HR=1.06, 95%CI= (0.85, 1.31)] (interaction P-value=0.043). Additionally, the significant association of non-freeway NO<sub>x</sub> and increased risk of developing OWOB was replicated in an independent CHS cohort sample of 2,474 participants and were followed with an average 6 years. Conclusion: Children exposed to higher non-freeway NO<sub>x</sub> were at higher risk of developing OWOB in later life.

## **P01.0920. Association between Health-Related Quality of Life and Air Pollution in Female in Korea**

Myung-Jae Hwang

*Myung-Jae Hwang<sup>1</sup>*

*1. Department of Social and Preventive Medicine, Sungkyunkwan University School of Medicine, Suwon, Korea (the Republic of).*

**Abstract:** Background; Exposure to air pollution in humans can lead to a reduction in physical and mental function before it progressed to disease development and morbidity. These adverse health effects are reflected health-related quality of life (HRQOL), the level of mental emotional and physical functioning in daily life. We assessed the impact subjective health status on exposure to air pollution in female in Korea. Methods; We recruited 2,836 women who were repeatedly surveyed three or more times in the Korean Health Panel (KHP) from 2009 to 2013. We matched each the EQ-VAS score of respondents with 24-hr averages of the air quality indexes and meteorological indexes obtained from the residence based on the date of survey by 8 administrative regions. Generalized linear mixed model was applied to estimate relative risks (RRs) and 95% confidence intervals (CIs) in single and multi-pollutants model. Results; The total number of cases over 5 years was 12,915. We found statistically significant relationships between education level, smoking status, marital status, weekly sleeping time, morbidity of disease, income and NO<sub>2</sub> level in the ambient air in female. The score was reduced 0.396 (-0.700 - -0.092) at lag 0 and 0.330 (-0.631 - -0.030) at lag 1 per 10 ppb in multi-pollutants model. Conclusion; This study suggested that short-term exposure to NO<sub>2</sub> could adversely affected health-related quality of life.

## **P01.0930. Are Ambient Volatile Organic Compounds Environmental Stressors for Heart Failure?**

Jinjun Ran

*Jinjun Ran<sup>1</sup>, Hong Qiu<sup>1</sup>, Shengzhi Sun<sup>2</sup>, Aimin Yang<sup>1</sup>, Linwei Tian<sup>1</sup>*

*1. School of Public Health, the University of Hong Kong, Hong Kong, Hong Kong.*

*2. School of Public Health, Brown University, Providence, RI, United States.*

**Abstract:** Background: Numerous epidemiological studies have demonstrated the health impacts of the criteria air pollutants on heart failure (HF). However, evidence on detrimental effects of ambient volatile organic compounds (VOCs) is insufficient. The present study aimed to estimate the short-term effects of ambient VOCs on emergency hospital admissions for HF in Hong Kong. Methods: Daily VOCs concentrations from April 2011 to December 2014 were collected from the Hong Kong Environmental Protection Department. Emergency hospital admissions for HF were obtained from the Hospital Authority of Hong Kong. Generalized additive model (GAM) integrated with the distributed lag model (DLM) was used to estimate the excess risks of HF hospitalizations associated with ambient concentrations of each VOC groups - alkane, alkene, alkyne, benzene and substituted benzene, while adjusting for time trend, seasonality, weather conditions, and calendar effect. Results: We observed short-term effects of alkyne and benzene on HF hospitalizations. The cumulative effect over 0-6 lag days (dlm0-6) for an IQR increment of alkyne (1.17ppb) was associated with 4.2% (95%CI: 1.18% to 7.26%) increases of HF emergency hospitalizations, while the corresponding effect estimate over dlm0-2 for benzene per IQR (0.43ppb) was 2.7% (95%CI: 0.39% to 5.04%). Each VOC group was significantly associated with emergency HF hospitalizations in men. Conclusions: Ambient volatile organic compounds, particularly alkyne and benzene, might be environmental stressors for heart failure in Hong Kong population, especially for men.

## **P01.0940. A Population-Based Birth Cohort Study of the Association between Childhood-Onset Asthma and Exposure to Industrial Air Pollutant Emissions**

Stephane Buteau

*Stephane Buteau<sup>1</sup>, Mariève Doucet<sup>1</sup>, Louis-Francois Tetreault<sup>3</sup>, Philippe Gamache<sup>1</sup>, Michel Fournier<sup>3</sup>, Allan Brand<sup>1</sup>, Tom Kosatsky<sup>2</sup>, Audrey Smargiassi<sup>4</sup>*

*2. British Columbia Centre for Disease Control, Vancouver, BC, Canada.*

*3. Montreal's Public Health Department, Montreal, QC, Canada.*

*4. Department of Environmental and Occupational Health, School of Public Health, University of Montreal, Montreal, QC, Canada.*

**Abstract:** Background: Studies of the association between air pollution and asthma onset have mostly focused on urban and traffic-related air pollution. We investigated the associations between exposure to industrial emissions and childhood-onset asthma in a population-based birth cohort in Quebec, Canada, 2002-2011. Methods: The cohort was built from administrative health databases. We developed separately for PM<sub>2.5</sub> and SO<sub>2</sub> different metrics representing children's time-varying residential exposure to industrial emissions: 1) tons emitted yearly by all industries within 2.5 km; 2) distance to the nearest "major emitter" ( $\geq 100$  tons/year) within 7.5 km; 3) wind and inverse-distance weighted emissions of the nearest major emitter within 7.5 km. To handle the large number of zeros (i.e., children unexposed) we decomposed the exposure variable into two covariates simultaneously included in the regression model: A binary indicator of exposure and a continuous exposure variable centered at the mean value among exposed children. We performed Cox models using age as the time axis, adjusted for gender, material and social deprivation and calendar year. We indirectly adjusted for unmeasured secondhand smoke. Results: The cohort included 722,667 children and 66,559 incident cases of asthma. Across the different exposure metrics, mean percentage changes in the risk of asthma onset in children exposed to the mean relative to those unexposed ranged from 4.5% (95%CI: 2.8, 6.3%) to 10.6% (95%CI: 6.2, 15.2%) for PM<sub>2.5</sub> and, from 1.1% (95%CI: -0.1, 3.3%) to 8.9% (95%CI: 7.1, 11.1%) for SO<sub>2</sub>. Indirect adjustment for secondhand smoke marginally influenced the associations. Among children exposed, the risk of asthma onset increased with the magnitude of the exposure for all metrics, except the distance to the nearest major emitter of SO<sub>2</sub>. Conclusion: In this population-based birth cohort, residential exposure to air pollutant emissions from industries was associated with childhood-onset asthma.

**P01.0950. Indoor and Outdoor Pollution: Assessment of PM2.5 in Yopougon (Abidjan, Cote D'ivoire)**

Ahua Kouao

*Ahua R. Kouao*<sup>1</sup>

*1. Public Health, University Felix Houphouet Boigny Cocody, Abidjan, Côte d'Ivoire.*

**Abstract:** Background: Biomass combustion is a major source of indoor air pollution. In Côte d'Ivoire, 30.5 % of the population in the urban areas use biomass for cooking. Few studies have investigated indoor and outdoor air pollution in urban area in West Africa. The aim of this study was to determine indoor and outdoor pollutants concentrations in household in Yopougon (Côte d'Ivoire). Methods: Indoor and outdoor air quality was investigated at two sites Andokoi and Lubrafrique in Yopougon. Questionnaires were used to collect demographic characteristic and exposure history in 109 households (Andokoi, n = 65; Lubrafrique, n = 44). Assessment of indoor and outdoor air quality were done simultaneous during 48 hours in each household with Quest EVM-7 device. Statistic test Chi square and multivariate logistic regression were used to compare the sites and association between independent variables with pollutants. Results: Average concentrations of indoor PM2.5 for Andokoi and Lubrafrique were respectively,  $38 \pm 21 \mu\text{g}/\text{m}^3$  and  $116 \pm 64 \mu\text{g}/\text{m}^3$ . Also, average concentrations of outdoor PM2.5 for Andokoi and Lubrafrique were  $108 \pm 88 \mu\text{g}/\text{m}^3$  and  $34 \pm 21 \mu\text{g}/\text{m}^3$  respectively. Indoor and outdoor concentration of PM2.5 at Andokoi were higher than concentration of PM2.5 at Lubrafrique ( $p= 0.00$ ). An association was found between both number of cooking times [6.70 (1.23 - 36.57)], smoking [0.05 (0.00 - 0.93)] and concentration of indoor PM2.5. Concentration of outdoor PM2.5 were associated with the closeness of household to industrial area [9.43 (1.54 - 57.58)], method of smoking fish/meat [15.05 (2.15 - 105.32)], indoor PM2.5 [6.78 (1.14 - 40.01)] and ambient temperature [34.32 (3.03 - 388.22)]. Conclusions: Average concentration of indoor and outdoor PM2.5 were often more than WHO guideline value for PM2.5 ( $25 \mu\text{g}/\text{m}^3$ ). We need to investigate the relationship between exposure to indoor household air pollution and respiratory diseases in the population.

## **P01.0960. Effect of Long-Term Exposure to Fine Particulate Matter on Incident Dyslipidemia: A Cohort Study**

Yacong Bo

*Yacong Bo<sup>1</sup>, Cui Guo<sup>1</sup>, Zilong Zhang<sup>1</sup>, Xiang Qian Lao<sup>1</sup>*

*1. School of Public Health and Primary Care, Faculty of Medicine, The Chinese University of Hong Kong, Hong Kong, Hong Kong.*

**Abstract:** Background: Evidence about effects of long-term exposure to fine particulate matter (PM2.5) air pollution on the development of dyslipidemia is limited. This study aimed to investigate the associations between long-term ambient PM2.5 exposure and incident dyslipidemia in a large cohort. Methods: We studied 76,618 participants aged 18 years or above from a cohort who participated in a standard medical examination program between 2001 and 2014 in Taiwan. The PM2.5 concentration at each participant's address was estimated using a satellite-based spatio-temporal model at a high resolution (1x1 km<sup>2</sup>). Cox proportional regression hazard model was used to examine the associations between long-term exposure to ambient PM2.5 and the development of dyslipidemia. Stratified and sensitivity analyses were further conducted to examine the potential modifiers and the stability of these associations. Results: Every 10 µg/m<sup>3</sup> increment in the 2-y average PM2.5 concentration was associated with an increase of 4% in the risk of dyslipidemia development [hazard ratio=1.04 (95%CI: 1.02-1.05)]. Compared to the participants with the 1st tertile of PM2.5 exposure, participants exposed to the 2nd and 3rd tertiles of PM2.5 were associated with a hazard ratio of 1.07 (95%CI: 1.05-1.10) and 1.09 (95%CI: 1.06-1.12) in incident dyslipidemia, respectively. Sensitivity analysis generally yielded similar results. Stratified analysis suggested that participants with diabetes had higher effects of long-term PM2.5 exposure on dyslipidemia development. Conclusion: Long-term exposure to ambient PM2.5 is associated with an increased risk of developing dyslipidemia. Global strategies on air pollution reduction are needed to prevent dyslipidemia development.

## **P01.0970. Spatial and Temporal Patterns of Ambient Ultrafine Particles (UFP) in Communities Along an Aircraft Arrival Trajectory**

Chloe Kim

*Chloe Kim<sup>1</sup>, Kevin J. Lane<sup>1</sup>, Matthew C. Simon<sup>1</sup>, Claire Schollaert<sup>1</sup>, John Durant<sup>2</sup>, Jonathan Levy<sup>1</sup>*

*1. Boston University School of Public Health, Department of Environmental Health, Boston, MA, United States.*

*2. Tufts University, Department of Civil and Environmental Engineering, Medford, MA, United States.*

**Abstract:** Background: Ultrafine particles (UFP) from aircraft are of concern due to their high emission rates and potential adverse health effects, but are challenging to characterize given their spatial and temporal variability. Recent studies report elevated UFP concentrations across large areas downwind from airports, but have not had sufficient data for source attribution. Our objective was to characterize aviation contributions to UFP concentrations under various meteorological conditions using highly-resolved flight activity data. Methods: We measured particle number concentration (PNC; a proxy for UFP) and meteorology from April to September 2017 at six ground-level sites that were varying distances from an arrival flight path into Boston Logan International Airport. Concurrent flight activity data were obtained from the U.S. Federal Aviation Administration. We compared PNC distributions as a function of meteorological conditions and flight activity, and constructed regression models for source attribution. Results: PNC distributions differed as a function of meteorological conditions and runway usage. Monitoring sites near the airport had similar hourly median PNC levels when the arrival runway was closed versus fully operational, but there was a 1-2 fold increase in 95th and 99th percentile PNC. Regression models provided insight regarding contributions of individual flights and dependence on meteorological conditions. Discussion: Our findings suggest a strong and intermittent contribution from arrival aircraft at sites in closer proximity (4~7km vs. 9~17km) to the airport. Further, diurnal patterns of PNCs, especially at the upper tails of the distribution, are suggestive of aircraft activity. Our site selection and availability of highly-resolved flight activity data, along with the use of real-time concentration measurements, reduces the potential confounding by traffic sources and allowed us to determine aircraft contributions to measured PNC.

**P01.0980. Acute Changes in Blood Pressure Following Controlled Exposures to Cookstove Air Pollution in the Subclinical Tests of Volunteers Exposed to Smoke (STOVES) Study**

Kristen Fedak

Abstract: Exposure to household air pollution from cookstoves is a top risk factor for disease globally; cardiovascular diseases make up about half of the burden. However, the association between household air pollution and cardiovascular effects is not well characterized; health assessments often rely on data from other sources (e.g. cigarette smoking, ambient fine particulate matter [PM<sub>2.5</sub>]). Evidence specifically for the cardiovascular impacts of wood smoke continues to be mixed. We conducted a controlled human exposure study to investigate acute responses in blood pressure following cookstove-generated pollution exposure. Forty-eight young, healthy subjects were assigned to six, two-hour exposures: five cookstove treatments at target PM<sub>2.5</sub> concentrations representative of the stove's emissions (liquid petroleum gas [LPG], 10ug/m<sup>3</sup>; semi-gasifier, 35ug/m<sup>3</sup>; fan rocket, 100ug/m<sup>3</sup>; rocket elbow, 250ug/m<sup>3</sup>; open fire, 500ug/m<sup>3</sup>) and a filtered air control (0ug/m<sup>3</sup>). Mixed models were used to estimate associations between treatments and blood pressure. At 24 hours post-exposure, systolic pressure was on average 2-3 mmHg higher for all treatments compared to the control, except the rocket elbow stove, which was not different than control. For example, the estimated difference for the LPG stove compared to control was 3.1 mmHg (95% CI, 1.0-5.3). No clear or consistent differences were observed for systolic pressure immediately post-exposure or three hours post-exposure, or for diastolic pressure at any time point or treatment. These results, combined with evidence from other research, suggest that short-term exposure to cookstove-generated air pollution may adversely impact blood pressure in healthy young adults, even at low PM<sub>2.5</sub> concentrations and for stove technologies considered to be some of the cleanest available in many locations worldwide. Further analyses will consider exposure-response and additional pollutants. [This abstract does not represent EPA policy.]

## **P01.0990. Chemical Composition and Emissions Factors for Cookstove Startup (Ignition) Materials**

Kristen Fedak

*Kristen Fedak<sup>1</sup>, Nicholas Good<sup>1</sup>, Jordyn Dahlke<sup>1</sup>, Amy Sullivan<sup>1</sup>, Arsineh Hecobian<sup>1</sup>, Jennifer L. Peel<sup>1</sup>, John Volckens<sup>1</sup>*

*1. Colorado State University, Fort Collins, CO, United States.*

**Abstract:** Exposure to household air pollution from residential cookstoves is a leading risk factor for disease globally. Previous work suggests that a disproportionate fraction of emissions can occur during cookstove startup; however, these data are limited to a few materials and pollutants. This study is the first to isolate emissions from cookstove startup across a range of startup materials and pollutants. Laboratory tests were conducted to measure emissions from commonly used cookstove startup materials: kerosene, plastic bags, newspaper, fabric, food packaging, rubber tire tubes, footwear, kindling, and wood shims. Tests were designed to isolate emissions from the startup material, using a generic cookstove to simulate a real-world cookstove startup process. We measured pollutants relevant to health and climate, including: carbon monoxide, carbon dioxide, methane, fine particulate matter mass (PM<sub>2.5</sub>), PM<sub>2.5</sub> elemental and organic carbon, volatile organic compounds (e.g., benzene, toluene), and carbonyls (e.g., formaldehyde, acetaldehyde). Emissions varied substantially across materials on a per-startup event basis. For example, PM<sub>2.5</sub> emissions were lowest for food packaging (8 mg/startup) and plastic bags (2 mg/startup) and highest for kerosene (496 mg/startup) and kindling (355 mg/startup). Carbon monoxide emissions ranged from 30 mg/startup (plastic bags) to 999 mg/startup (kerosene). Emissions of carcinogens and other hazardous pollutants similarly varied by one to two orders of magnitude between materials. Our results demonstrate that startup materials can contribute substantially to the overall emissions from a cooking event. Startup material choice is particularly important for cleaner stove/fuel combinations, where emissions from the main cooking event are lower and the contribution from startup material is proportionally larger. The incremental increase in emissions from startup materials is expected to have a larger marginal health impact with cleaner stoves.

## **P01.1010. Comparing Air Pollution Modelling and Monitoring for Bushfire Smoke Health Impact Assessment in Australia**

Joshua Horsley

Abstract: Fine particulate matter (PM<sub>2.5</sub>) is causally associated with cardiovascular and respiratory morbidity and mortality. Over recent decades the Sydney Greater Metropolitan Region population of five million have been repeatedly exposed to extreme levels of PM<sub>2.5</sub> in smoke from bushfires, planned and unplanned. To date, estimates of historical exposure and related health effects have been based only on sparse monitors. The aim of this study is to compare existing estimates of exposure and health impact with those based on Chemical Transport Modelling (CTM) and blended surfaces; and to determine whether any differences are important for understanding the public health impact of bushfire smoke. Three methods of estimating PM exposure attributable to bushfires in Sydney will be compared. First, exposure based on only PM monitor interpolation will be compared to exposure based only on CTM. The former of these assessments is the subject of a paper under embargo until mid-April 2018. Comparisons of the magnitude and distribution of exposure and health effects will be presented. Developing results from a third 'blended' exposure surface will also be presented. This third exposure estimate is based on Bayesian blending of the monitor and CTM surfaces. A main aim of this work is to determine whether CTM predictions of future exposure can be bias-corrected based on the previous relationship between monitors and CTM, i.e. can predictions of future exposure be improved by taking into account recent model performance? Health impact will be quantified in terms of attributable premature mortalities and hospitalisations for cardiovascular and respiratory disease. The distribution and magnitude of these health effect estimates from the three exposure models will be compared to determine if there is a meaningful difference for understanding the public health impact of bushfire smoke.

## **P01.1020. A Multi-Provincial Study of Air Pollution Exposure in Rural and Peri-Urban China**

**Abstract:** Background: Coal and biomass burning for household cooking and heating is a major source of exposure to air pollutants including fine particulate matter (PM<sub>2.5</sub>). Compared with urban air pollution, little is known about air pollution exposures in rural and peri-urban settings, particularly among men. Objective: Assess personal exposures to PM<sub>2.5</sub> among men and women ages 40-79 living in peri-urban villages in northern (Beijing, Shanxi) and southern China (Guangxi). Methods: We enrolled 782 participants into the INTERMAP China Prospective Study from these three regions and measured their integrated gravimetric personal exposures to PM<sub>2.5</sub> (Apex pumps; Harvard PEMs; 37 mm PTFE filters) for 2 days in heating and non-heating seasons and also collected information on fuel and energy use patterns. Results: Geometric mean daily exposures to PM<sub>2.5</sub> across sites and seasons ranged from 60 (95% CI [56, 64], Guangxi - heating season) - 134 (95% CI [122, 147], Shanxi - heating season) ug/m<sup>3</sup>. A seasonal difference was observed in the northern sites (GM = 96 ug/m<sup>3</sup>, 95% CI [90, 101] in heating versus 88 ug/m<sup>3</sup> [83, 94] in non-heating). Exposures were highest in Shanxi (GM = 120 ug/m<sup>3</sup>, 95% CI [113, 128]), followed by Beijing (93 ug/m<sup>3</sup> [87, 99]) and Guangxi (60 ug/m<sup>3</sup> [56, 64]). This trend persisted across season and gender. The proportion of participants using solid fuels was highest in Beijing (95%), followed by Shanxi (75%), and Guangxi (62%). Notably, individuals not using solid fuels for cooking and heating (GM = 92 ug/m<sup>3</sup> [83, 102]) had similar exposures to individuals using solid fuels (93 ug/m<sup>3</sup> [89, 97]). Conclusion: Use of solid fuels has persisted across northern and southern China. Exposures across all demographic groups and seasons exceeded the WHO 24-h air quality guideline of 25 ug/m<sup>3</sup>. On average, exposures in southern China were half that of northern China, where heating is an important energy use practice.

## **P01.1030. Incorporating Snow and Cloud Fractions in Random Forest to Estimate High Resolution PM2.5 Exposures in New York State**

Abstract: Satellite aerosol optical depth (AOD) has been widely used to estimate the ground-level PM2.5 concentrations, but cloud/snow covers often lead to a large proportion of non-random missing AOD, causing difficulties in generating fully covered and unbiased PM2.5. Among the current approaches to address the data gap issue, few have considered the cloud-AOD relationship and none of them considered the snow-AOD relationship. This study aims to examine the influence of satellite-retrieved snow cover on AOD and PM2.5, and to generate accurate PM2.5 predictions in the areas with extensive snow cover. We chose New York State as our study domain since AOD missing rate here was ~ 90% and a large part of them was due to snow cover in winter. To estimate the missing AOD, a gap-filling model with cloud/snow fractions and other meteorological covariates was developed based on random forest algorithm. By applying this model, daily AOD dataset with 1 km resolution in 2015 was generated with complete spatial coverage. The "out-of-bag" R2 of the model averaged 0.93 with an interquartile range from 0.90 to 0.95. A random forest-based PM2.5 prediction model incorporating gap-filled AOD, land use, and meteorological terms was then developed to predict 1 km ground-level PM2.5 in 2015. Ten-fold cross-validation revealed good model performance with an R2 of 0.82. In the gap-filling model, snow fraction had a significantly higher importance in snow season of 2015. Models fitted with/without snow fraction also showed discernable PM2.5 pattern changes, further confirming the importance of this parameter. Compared to methods without explicitly considering cloud and snow cover, our PM2.5 prediction surfaces displayed more spatial details and reflected small-scale terrain-driven PM2.5 patterns. Our method can be generalized to the areas with extensive snow cover for producing reliable PM2.5 predictions with high resolution and complete coverage.

## **P01.1040. Neighborhood Scale Health Impacts from PM2.5 in Four United States Metropolitan Areas**

Alexander Lindahl

*Alexander J. Lindahl<sup>1</sup>, Susan C. Anenberg<sup>1</sup>*

*1. Environmental and Occupational Health , George Washington University, Milken Institute School of Public Health, Washington, DC, United States.*

**Abstract:** Background: Epidemiological cohort studies have found associations between long-term exposure to fine particulate matter (PM2.5) and increased mortality as well as associations between short-term PM2.5 and asthma exacerbation. Findings from these studies have been used to quantify health impacts due to PM2.5 and other air pollutants in the US, but have primarily used county, state, or national level disease information. Objective: The objective of this study is to evaluate health impacts of PM2.5 at a finer spatial resolution than has previously been estimated (0.01x0.01-degree), utilizing tract level disease rates and satellite-derived exposure estimates in four major US metro areas: Boston, Los Angeles, New York City, and Washington, DC. Methods: We estimated PM2.5-related asthma emergency room visits and cause specific mortality for stroke, lung cancer, and COPD using epidemiologically-derived health impact functions. Census tract level disease- and age-specific baseline incidence rates were derived using tract-level to city-level disease rate ratio scaling. Tract surveillance data and mortality rates were obtained through the CDC's 500 Cities Project and WONDER database, respectively. Relative risk estimates linking PM2.5 with health outcomes were drawn from a recent American Cancer Society study. The estimated health impacts were calculated using the environmental Benefits Mapping and Analysis Program-Community Edition v1.3 (BenMAP-CE v1.3). High resolution (0.01x0.01-degree) PM2.5 concentrations are from a global dataset integrating satellite remote sensing with chemical transport modeling and in situ observations. Results: We show computed asthma emergency room visits and cause-specific mortality attributable to PM2.5 on 0.01x0.01-degree grid in four major US cities. PM2.5-attributable health impacts vary considerably between tracts within these metropolitan areas. Neighborhoods experiencing particularly large health impacts from PM2.5 exposure are highlighted.

## **P01.1050. Syria and Yemen Wars and Their Impact on Atmospheric NO<sub>2</sub>**

Aigerim Maksot

*Aigerim M. Maksot<sup>1</sup>, Mehdi Amouei Torkmahalleh<sup>1</sup>, Lyazzat Kulmukanova<sup>1</sup>, Zhuldyz Darynova<sup>1</sup>, Zere Bekzhanova<sup>1</sup>, Gulbanu Tillabek<sup>1</sup>*

*1. Chemical Engineering, Nazarbayev University, Astana, Kazakhstan.*

Abstract: Vertical Column Density (VCD) of NO<sub>2</sub> over the atmosphere of the Syrian Arab Republic and Yemen during the 2005-2016 period was studied to understand the potential impact of the war on the atmosphere of the two countries as well as their neighbour regions. The concentration data of NO<sub>2</sub> was retrieved from the satellite data collected by the Ozone Monitoring Instrument (OMI) on the board of Aura Satellite and analyzed through the NCAR Command Language and Giovanni web-based application. The current study investigated the impact of energy sector, social and geopolitical situations in the two countries on NO<sub>2</sub> concentrations before and during the war. A trend of VCDs in the aforementioned countries imply that a war has an impact on NO<sub>2</sub> concentrations, thus a thorough analysis of the dynamics of NO<sub>2</sub> concentrations over the atmospheres of countries experiencing war is of the essence. An analysis of the Syrian and Yemeni atmospheres before the war period showed a slightly increasing trend of NO<sub>2</sub>, which is a typical observation for oil-based countries experiencing the growth of the population, vehicles use, and the development of the industry. The war impact on the amount of NO<sub>2</sub> in Syria can be noticed by a sharp decrease of nitrogen dioxide from  $1.83 \times 10^{15}$  molecules/cm<sup>2</sup> till  $1.15 \times 10^{15}$  molecules/cm<sup>2</sup> when the vigorous armed interactions have begun, however, the VCD of NO<sub>2</sub> gradually increases in Yemen during the war from  $0.56 \times 10^{15}$  molecules/cm<sup>2</sup> in 2015 till  $0.66 \times 10^{15}$  molecules/cm<sup>2</sup> in 2017. The main effect of war can be explained by the considerable reduction of the population caused by refugee migration, termination of the energy sector and fossil fuel production due to disturbances in building infrastructure. Also, an important aspect of the significant number of chemical attacks and explosions during the war affect the concentration of NO<sub>2</sub>.

**P01.1060. Escape to America: Adapting European Study for Cohorts for Air Pollution Effects (ESCAPE) Methods to the Desert Southwestern U.S.**

Nathan Lothrop

*2. Asthma and Airways Disease Research Center, University of Arizona, Tucson, AZ, United States.*

Abstract: The influence of air pollution on respiratory illnesses is well-documented, however few long-running respiratory studies have measured air pollution at participant homes or other locations. To retrospectively predict air pollution exposures, various approaches have been taken, including dispersion modeling, geostatistical interpolation, and land use regression (LUR) modeling. LUR modeling as per the European Study for Cohorts for Air Pollution Effects (ESCAPE) has been used in >30 locations in Europe, but never in the US nor validated with values measured >10 years prior. In this study, we tested the ability of LUR models to predict air pollutant measures from nearly 30 years earlier in Tucson, AZ. Using ESCAPE sampling methods, the Tucson Air Pollution Study (TAPS) sampled NO<sub>2</sub> in 40 homes and PM<sub>2.5</sub> and PM<sub>10</sub> in half of those homes for 3 two-week periods from 2015-2016 in Tucson, AZ. Using comparable sampling methods, the Pima County Workers Study (PCWS) measured NO<sub>2</sub> in 39 homes and PM<sub>2.5</sub> and PM<sub>10</sub> in 17 homes for 2 one-week periods in 1987 in Tucson, AZ. LUR models were developed for each pollutant in each dataset and internally validated with ESCAPE methods. Then, TAPS-based LUR models predicted PCWS pollutant levels. During internal validation, TAPS-based LUR models performed better than PCWS-based models: for TAPS, adjusted R<sup>2</sup> values for NO<sub>2</sub>, PM<sub>2.5</sub>, and PM<sub>10</sub> were 0.75, 0.55, and 0.68, respectively, versus, 0.47, 0.25, and 0.21 for PCWS. In retrospective prediction, adjusted R<sup>2</sup> values (root-mean-square error) for TAPS-based LUR models for NO<sub>2</sub>, PM<sub>2.5</sub>, and PM<sub>10</sub> were 0.37 (10.7 ppb), 0.70 (27.6 µg/m<sup>3</sup>), and 0.30 (17.3 µg/m<sup>3</sup>), respectively. While predictions for PM<sub>2.5</sub> and PM<sub>10</sub> levels had limited success, the NO<sub>2</sub> predictions were within the measured range but generally under-predicted (predicted vs. measured ranges: 2.83 - 8.41 vs. 5.17 - 24.8 ppb). Our project shows promise for using LUR to retrospectively model air pollution levels measured nearly 30 years earlier.

## **P01.1070. Spatial and Temporal Variation of Lung Deposited Surface Area at Kerbside Locations in a Metropolitan City**

**Abstract:** Traffic related air pollution is one of the great concerns in urban areas in low- and middle-income countries. With continued efforts in reducing particulate mass concentrations, scientists have started looking into ultrafine particulates (UFPs) and its characterisation. As UFPs have larger surface area, they can deeply penetrate into respiratory tract, causing adverse health issues. A few recent studies have considered lung deposited surface area (LDSA), particle number concentration (PNC) along with black carbon (BC) and PM<sub>2.5</sub> to characterise the UFPs. The aim of this study is to examine the kerbside concentrations of UFPs and its variation with real-world driving conditions in Mumbai. Kerbside real-time measurements of LDSA, PNC, BC and PM<sub>2.5</sub> were conducted on major roads, expressway and urban background from Jun 2016 to Feb 2017 in North Central Mumbai. All measurements were done on weekdays during rush (8:00-12:00) and non-rush (12:00-16:00) hours. Near expressway, average concentration of LDSA and PNC are 351 and 26,000 #/cm<sup>3</sup>, respectively. Corresponding levels near major roads are 237 and 20,000 #/cm<sup>3</sup>, respectively. LDSA is 2.5-3.5 times and PNC is 3.5-4.5 times higher than that of background whereas for BC and PM<sub>2.5</sub> it is 2.0-3.0 times and 3.0-4.5 times higher than background. Among the pollutants LDSA and PNC show a good correlation (Spearman  $\rho=0.87$ ), while LDSA and BC illustrate a weak correlation ( $\rho=0.27$ ). The correlation is 1.2-2.5 time higher on expressways compared to the major roads. The average kerbside/background ratio of PM<sub>2.5</sub> is 1.2-1.9 times lesser than that of LDSA or PNC. These findings suggest differential impact of on-road traffic volume, driving conditions and traffic composition on the pollutants' levels and higher levels of exposure to ultrafine particulates near roads.

## **P01.1080. Relationship between Low Birthweight and Air Pollution in a Port Brazilian City**

Maura Eduarda Brandao

*Maura Eduarda L. Brandao<sup>1</sup>, Alfésio Braga<sup>2</sup>, Lourdes Martins<sup>2</sup>, Luiz Alberto A. Pereira<sup>1</sup>*

*2. Unisantos, Santos, Sao Paulo, Brazil.*

**Abstract:** Santos is a seaboard Brazilian city recognized by its port activity. Because of proximity to the city of Sao Paulo, the road and rail infrastructure and the large transportation operation, there is an intense cargo handling capable of emitting all kinds of toxic and polluting waste. Some studies have pointed out the relationship between air pollution and perinatal outcomes. Pollutant gases such as CO, SO<sub>2</sub>, NO<sub>x</sub> e O<sub>3</sub> and particulate matter PM<sub>2,5</sub>, PM<sub>10</sub> have been cited as factors involved in such outcomes. Therefore, the present study aims to evaluate the association between atmospheric pollutants monitored by the São Paulo State Environmental Agency (CETESB) and perinatal outcomes in the city of Santos from January 2011 to December 2015. **METHODS:** It is a historical cohort study of pregnant women. Birth weight and information on mother and pregnancy were obtained at the Brazilian "Born Alive National Information System" (SINASC, in Portuguese). Daily records of air pollutants (PM<sub>10</sub>, PM<sub>2.5</sub>, NO<sub>2</sub>, SO<sub>2</sub> and O<sub>3</sub>), temperature and relative humidity of air, for the study period, were obtained from CETESB. Associations between low birth weight and air pollutants mean levels at each gestational trimester were investigated using multiple logistic regression model controlled by the variables: maternal education, prenatal care, marital status, maternal age, anomalies, pregnancy type and number of dead children. **RESULTS:** The effects for PM<sub>2,5</sub> and PM<sub>10</sub> in the third trimester for the last quartile (19,59 µg/m<sup>3</sup> and 38,64 µg/m<sup>3</sup> respectively) were found the risk of 1,18 (CI 95% 1,01; 1,38 for PM<sub>2,5</sub> and 1,01; 1,42 for PM<sub>10</sub>). **CONCLUSION:** Although air pollution levels are lower than the other metropolitan areas in Brazil, the results show an effect on low birth weight at higher concentrations suggesting that not only burning of fossil fuels but port activity also can contribute in the emission of organic particulate matter such as soybeans, corn, wheat, etc.

## **P01.1100. Improvement of LUR Model Predictions Using Chemistry-Transport Model Estimates**

Frauke Hennig

*Frauke Hennig<sup>1</sup>, Sarah Lucht<sup>1</sup>, Barbara Hoffmann<sup>1</sup>*

*1. Environmental Epidemiology, Institute for Occupational, Social and Environmental Medicine, Heinrich-Heine University, Duesseldorf, Germany.*

**Abstract:** Background: In the German Ruhr area, two commonly used air pollution (AP) models are available and yield different long-term AP estimates. While the Land Use Regression (LUR) estimates point-specific AP, the EUROpean Air pollution Dispersion Chemistry Transport Model (EURAD-CTM)) represents background AP within a grid of 25km<sup>2</sup>. We combined both models by considering AP values from the EURAD-CTM as potential predictors for the LUR-model to estimate long-term AP for PM<sub>2.5</sub>, PM<sub>10</sub>, and NO<sub>2</sub>. Methods: The original LUR model was developed within the European Study of Cohorts on Air Pollution Effects (2009) using a standardized strategy to select predictors from traffic and land use predictor variables of a GIS database. For the new LUR model, we applied the same variable selection strategy, additionally including long-term AP estimates (mean PM<sub>2.5</sub>, PM<sub>10</sub> and NO<sub>2</sub> for 2006-2008) from the EURAD-CTM as potential predictors. Results: Original predictors for PM<sub>2.5</sub> included total heavy-duty traffic load on all roads within a 1000m buffer (heavytrafload1000), surface of industry within 5000m (industry5000), population density within 1000m (pop1000) and the x-coordinate (R<sup>2</sup>=0.85), while the new model included pop1000, CTM-PM<sub>2.5</sub>, heavy traffic major road within 1000m, industry5000 and the y-coordinate (R<sup>2</sup>=0.93). Original PM<sub>10</sub> predictors were heavytrafload1000 and pop1000 (R<sup>2</sup>=0.66), while the new PM<sub>10</sub> model included road length within 1000m, CTM-PM<sub>10</sub>, surface area of high density residential land within 5000, urban greenness within 300m and industry300 (R<sup>2</sup>=0.95). The new NO<sub>2</sub> model did not change from the original, including industry5000, pop100, surface of port within 1000m and traffic load within 100m (R<sup>2</sup>=0.88). Conclusion: Offering CTM-AP estimates as candidates changed LUR-model predictors for PM<sub>2.5</sub> and PM<sub>10</sub> and improved the model fit considerably. The agreement with actual AP measurements and the effect on health outcomes of these new LUR model has to be evaluated in future studies.

## **P01.1120. The Causal Response of Wellbeing to Air Pollution: Does the Metric of Wellbeing Matter?**

Daniel Bi

*Daniel Bi<sup>1</sup>, Jiongchao Ding<sup>1</sup>, Xingyu Liu<sup>2</sup>, Jianxun Yang<sup>2</sup>, Zheng Zhu<sup>1</sup>, Miaomiao Liu<sup>2</sup>*

*1. Nanjing Foreign Language School, Nanjing, China.*

*2. State Key Laboratory of Pollution Control and Resource Reuse, School of the Environment, Nanjing University, Nanjing, China.*

**Abstract:** Introduction: Various wellbeing metrics adopted by researchers made it less possible to conclude the extent to which a change of wellbeing on a particular metric caused by air pollution could be generalized to another. Additionally, exiting evidences based on the data from household survey were challenged by uncontrolled confounders and limited capacity on explaining causal relationships. Methods: We creatively introduced an environmental psychological experiment paradigm to investigate the wellbeing response in different metrics to PM2.5. Images matched with varied PM2.5 as the stimulus were viewed by 110 participants in a quiet lab. E-prime 3.0 recorded participants' immediate wellbeing response in metrics of Self-Assessment Manikin (SAM) and annoyance after each stimulus. Participants are divided into four groups by whether they were told the experimental objective and whether there were landmarks in the background of pictures to examine the stigma effect of air pollution and the interference of picture background, respectively. Results and Discussion: Regarding the annoyance, critical PM2.5 were 42-50  $\mu\text{g}/\text{m}^3$ . Under critical interval PM2.5 didn't cause additional annoyance while above critical levels the annoyance increased by 1.95% per 10  $\mu\text{g}/\text{m}^3$  PM2.5 increase. Similar patterns were found in valance and arousal of SAM. The valance increased by 1.56% per 10  $\mu\text{g}/\text{m}^3$  PM2.5 increase, with a broader critical interval of 42-65  $\mu\text{g}/\text{m}^3$  where the valance shifted from positive ratings (score $\geq$ 5) to negative ones (score $<$ 5). The arousal presented a U curve with the bottom level located in 42-50  $\mu\text{g}/\text{m}^3$ . Even using different wellbeing metrics, the same findings were concluded that PM2.5 caused negative wellbeing consequences with the threshold of 42-65  $\mu\text{g}/\text{m}^3$ . Participants who were told the objective reported significantly lower valance and higher annoyance than the counterpart, which proved the stigma effect. All findings were independent from the interference of picture background.

## **P01.1130. Air Quality Changes after Hong Kong's Shipping Emission Policy: An Accountability Study**

Tonya Mason

*Tonya G. Mason<sup>1</sup>, King Pan Chan<sup>1</sup>, Shengzhi Sun<sup>2</sup>, Hong Qiu<sup>1</sup>, Yang Yang<sup>1</sup>, Benjamin Barratt<sup>3</sup>, Linwei Tian<sup>1</sup>*

- 2. School of Public Health, Brown University, Providence, RI, United States.*
- 3. Environmental Research Group, King's College London, London, United Kingdom.*

**Abstract:** Background: On July 1st 2015, Hong Kong became the first city in Asia to enforce a policy that regulates emissions from ships. However, adequate scientific evidence to evaluate the environmental impact of the policy is limited. Hence, we aimed to conduct an accountability study on the current shipping emission policy, assessing the improvement of ambient air quality.

**Method:** Interrupted time series (ITS) was the chosen study design. In a series of segmented regression models, pre- intervention to post intervention changes in ambient air quality at Hong Kong's major shipping port Kwai Chung (KC) were evaluated; by studying the level and slope changes in the average monthly concentration of sulfur dioxide (SO<sub>2</sub>), respirable particulate matter (RSP), nitrogen dioxide (NO<sub>2</sub>) and Ozone (O<sub>3</sub>). Regression modeling was also done on pollution concentrations recorded at a background station (Tai Po), that was defined as a control station for the study. The policy was further evaluated using cumulative sum (CUSUM) charts. Results: Our segmented regression analysis revealed a significant decline in mean monthly SO<sub>2</sub> concentration at the Kwai Chung (KC) station post policy ( $\beta_2 = -10.092$  with a  $P = 0.000401$ ). No significant concentration decrease post policy was discovered for the other pollutants (RSP, NO<sub>2</sub>, O<sub>3</sub>) or for any of the pollutants recorded from the control station, Tai Po (TP). Visually, the CUSUM charts displayed a significant decrease in sulfur dioxide (SO<sub>2</sub>) concentration (46.33%) at the Kwai Chung (KC) monitoring station post policy; and at the TP station, it showed SO<sub>2</sub> declining way before the policy was implemented. Conclusion: Enforcement of the shipping emission policy was successful at reducing SO<sub>2</sub> at Hong Kong's major shipping port KC. Our study demonstrated an efficient approach to conduct an accountability study and provides substantial evidence about the benefits of implementing marine emission policies.

## **P01.1140. Chemical Composition and Oxidative Potential Analysis of Inhalable Road Dust in Toronto**

**Abstract:** In many cities, traffic combustion emissions are decreasing as a result of more stringent emissions standards and resulting technological improvements. However, non-tailpipe emissions have been neglected and their relative contribution to total traffic-related particle emissions is expected to increase in the upcoming years. The chemical composition of non-tailpipe particulate matter has been reasonably well established. However, too little is known about the toxicity of non-tailpipe emissions and the road dust they produce. Road dust contains a mixture of particles from several sources such as road surface wear, soil, tire wear, and brake wear. It can be resuspended by wind or traffic turbulence and thereby pose a threat to public health. This presentation will focus on the relationship between inferred toxicity and the chemical composition of inhalable road dust (PM<sub>2.5</sub> and PM<sub>10</sub>) from different districts within Toronto. Road dust was collected from residential roads, highways, arterial roads, underground parking garages, ground parking area, and urban background sites. Size-resolved inhalable road dust samples were resuspended onto filters through a custom-built apparatus. The oxidative potential of PM<sub>2.5</sub> and PM<sub>10</sub> in road dust is being determined with the acellular dithiothreitol assay to infer toxicity. The metal and organic composition of PM<sub>2.5</sub> and PM<sub>10</sub> in road dust are being determined and source apportionment will be performed to link the inferred toxicity back to specific sources. This work will improve our understanding about the toxicity of non-tailpipe emissions, and also give deeper insights into the relationships between the oxidative potential of road dust, its chemical composition and its contributing sources.

## **P01.1150. Review on Ultrafine Particle Health Effects**

Simone Ohlwein

*Simone Ohlwein<sup>2</sup>, Ron Kappeler<sup>1</sup>, Meltem Kutlar Joss<sup>1</sup>, Nino Küenzli<sup>1</sup>, Barbara Hoffmann<sup>2</sup>*

*1. Swiss Tropical and Public Health Institute, Department of Epidemiology and Public Health, University of Basel, Basel, Switzerland.*

*2. Institute for Occupational, Social and Environmental Medicine, Medical Faculty, Heinrich-Heine University Düsseldorf, Düsseldorf, Germany.*

**Abstract:** Background: Due to their small size, inhaled ultrafine particles (UFPs) may enter into alveoli and are even capable of penetrating cell membranes. Toxicological studies suggest that UFPs contribute to the development and progression of various diseases. However, epidemiological evidence for health effects of UFPs is scarce. The aim of this project is to give an overview of the epidemiological literature on the effects of UFPs on health. Methods: We conducted a systematic literature review searching MEDLINE and LUDOK data bases (time period January 2011 - May 2017) as well as a by hand search for review articles and conference proceedings. We focused on epidemiologic studies that investigated health effects of UFPs, included quantitative effect measures and had a common UFPs-measure. Data extraction and quality assessment using standard instruments was conducted by two reviewers. Results: Overall, 85 unique references were included in the review. Most of these studies were conducted in North America (n=37) or Western Europe (n=27). The majority of the studies investigated short-term effects (n=75). Ten studies investigated long-term associations. Short-term studies were dominated by panel studies with repeated measures, scripted exposure studies and time-series studies. The investigation of health effects in epidemiological studies has substantially developed during the last 7 years. Specifically, the more recent studies have undertaken efforts to control for co-pollutants in order to identify independent effects of UFPs. Despite the advances in the field, the evidence on health effects remains inconclusive or insufficient for most of the studied outcomes. Conclusions: A future challenge is the development of enhanced spatiotemporal models that are able to contribute to a more precise exposure assessment across larger areas and incorporate multipollutant models to estimate independent UFP effects.

**P01.1160. The Cardiorespiratory Impacts of Long-Term Ambient Air Pollution Exposure in China: Assigning Individual Pollutant Exposures within a Large Prospective Cohort Study**

Katherine Newell

*Katherine Newell<sup>1</sup>, Neil Wright<sup>1</sup>, Chrstiana Kartsonaki<sup>1</sup>, Om Kurmi<sup>2</sup>, Zhengming Chen<sup>1</sup>, Hubert Lam<sup>1</sup>*

*1. Nuffield Department of Population Health, University of Oxford, Oxford, United Kingdom.*

*2. Population Health Research Institute, McMaster University, Hamilton, ON, Canada.*

Abstract: Research quantifying the long-term health effects of ambient air pollution (AAP) exposure in China is scarce, limited by the need for large prospective cohorts plus assignment of individual AAP exposure. Existing studies often lack these accurate measures of individual exposure. We aimed to use spatio-temporal models to assign AAP exposure to participants within an existing prospective cohort study, the China Kadoorie Biobank (CKB). This abstract describes a pilot study using data from Suzhou, one of the 10 CKB regions. We obtained daily measurements of coarse and fine particulate matter (PM<sub>10</sub>, PM<sub>2.5</sub>), sulphur dioxide (SO<sub>2</sub>), nitrogen dioxide (NO<sub>2</sub>), carbon monoxide (CO), and ozone (O<sub>3</sub>), from 13 fixed-site monitors in Suzhou, between 2013 and 2015. We also incorporated the spatial covariates of elevation, land use, and distance to nearest motorway. We applied Bayesian modelling using the Integrated Nested Laplace Approximation (INLA) approach to predict pollutant levels for 81 assessment centres matched to 53,260 participants, each living within approximately 1km of their respective centre. Predicted AAP estimates at each centre can then be used as proxies for individual exposure in further analyses of adverse health impacts. Predicted exposures will subsequently be incorporated as time-varying covariates in Cox proportional hazards models, examining the risk of cardiorespiratory (ICD10: I00-I99/J00-J99) mortality and morbidity associated with long-term AAP exposure. We will also be able to incorporate a wide range of potential confounders provided within CKB. AAP exposure measures that we obtain on a finer temporal and spatial resolution will allow us to minimise exposure assessment bias. Combined with the high data quality of CKB and availability of numerous potential confounding variables, this research will allow us to examine cardiorespiratory health impacts of long-term AAP exposure more accurately than previous studies.

**P01.1170. Short-Term and Long-Term Exposures to Fine Particulate Matter Constituents and Health: A Systematic Review and Meta-Analysis**

Yang Yang

Yang Yang<sup>1</sup>, Hualiang Lin<sup>2</sup>, Linwei Tian<sup>1</sup>

1. School of Public Health, The University of Hong Kong, Hong Kong, Hong Kong.

2. Sun Yat-sen University, Guangzhou, China.

**Abstract:** Background: Being a mixture of heterogeneous components, fine particulate matter (PM<sub>2.5</sub>) has been observed to pose varying magnitudes of health effects by season and region. It remains largely unknown which components were the most harmful to human health. We conducted a meta-analysis to explore the health effects of short term and long term exposures to different constituents of PM<sub>2.5</sub>. Methods: A systematic literature search was conducted to obtain relevant studies as of October 31, 2017. We applied a random-effects meta-analysis to estimate the overall health effects for each constituent. Results: Significant associations were observed between several PM<sub>2.5</sub> constituents and different health endpoints. Black carbon (BC) and organic carbon (OC) were most robustly and consistently associated with all natural and cardiovascular mortality and morbidity. Other potential toxic constituents including nitrite, sulfate, Zn, Si, Fe, Ni, V, and K were associated with cardiovascular health, and nitrite, sulfate and V were relevant for respiratory health endpoints. The results were robust when we restricted to studies with PM<sub>2.5</sub> mass being controlled. Conclusions: Our analysis suggests that BC and OC are important detrimental components of PM<sub>2.5</sub>, and other constituents are probably hazardous to human health, but more studies are warranted to further confirm their health effects.

## **P01.1190. Short-Term Effects of Fine Particulate Matter and Ozone on the Cardiac Conduction System in Patients Undergoing Cardiac Catheterization**

**Abstract:** Background/Aim: Air pollution-induced changes in cardiac electrophysiological properties could be a pathway linking air pollution and cardiovascular events. Yet, evidence of air pollution effects on the cardiac conduction system is incomplete. We investigated short-term effects of particulate matter  $\leq 2.5 \mu\text{m}$  in aerodynamic diameter (PM<sub>2.5</sub>) and ozone (O<sub>3</sub>) on cardiac electrical impulse propagation and repolarization as recorded in surface electrocardiograms (ECG). Methods: We analyzed repeated 12-lead ECG measurements performed on 5,819 patients between 2001 and 2012. The participants came from the Duke CATHGEN Study who underwent cardiac catheterization and resided in North Carolina, United States (NC, U.S.). Daily concentrations of PM<sub>2.5</sub> and O<sub>3</sub> at each participant's home address were predicted with hybrid air quality exposure models. We used generalized additive mixed models to investigate the associations of PM<sub>2.5</sub> and O<sub>3</sub> with the PR interval, QRS interval, heart-rate-corrected QT interval (QTc), and heart rate (HR). The temporal lag structures of the associations were examined using distributed-lag models. Results: We observed four-day lagged increases in the PR interval of 0.17% (95%CI: 0.02%-0.33%) and 0.34% (0.10%-0.57%), respectively, by interquartile increments of PM<sub>2.5</sub> (7.0  $\mu\text{g}/\text{m}^3$ ) and O<sub>3</sub> (19.4 ppb); the associations remained significant up to 7-8 days after exposure. Elevated PM<sub>2.5</sub> was also associated with increases in the QTc interval lagged by three and four days, and increases in HR lagged by one and two days. Significant effects were found on all investigated ECG parameters when analyses were restricted to exposure levels below the current U.S. National Ambient Air Quality Standards. Conclusions: In patients undergoing cardiac catheterization, short-term exposure to air pollution was associated with a delay in atrioventricular conduction and ventricular repolarization, as well as increased heart rate. This abstract does not necessarily reflect EPA policy.

## **P01.1200. Associations between Ambient and Indoor PM2.5 Exposure and Cooking Fuel on Insulin Resistance in the PURSE-HIS Cohort**

Kevin Lane

*Devashri Salvi<sup>1</sup>, Kevin J. Lane<sup>1</sup>, Kalpana Balakrishnan<sup>2</sup>, Sadagopan Thanikachalam<sup>2</sup>, Mohan Thanikachalam<sup>3</sup>*

*2. Sri Ramachandra University, Chennai, Tamil Nadu, India.*

*3. Tufts University School of Medicine, Boston, MA, United States.*

**Abstract:** Introduction: Evidence suggests that chronic exposure to ambient PM2.5 is associated with the prevalence and incidence of Diabetes Mellitus. This relationship has not been well explored in India, where there is an increased prevalence of diabetes and elevated exposures to PM2.5. Our study assessed associations between ambient and indoor PM2.5 exposure and cooking fuel type with insulin resistance as measured by the homeostasis model assessment of insulin resistance (HOMA-IR) method, in the Population study of Urban, Rural, Semi-urban Endovascular disease and Holistic Intervention Study (PURSE-HIS) in Tamil Nadu, India. Method: HOMA-IR was assessed in 8080 randomly selected participants. Estimates of ambient PM2.5 were derived using a combination of satellite retrieved aerosol optical depth and chemical transport modelling for 2010. For a subset of the cohort (n = 430), we measured indoor PM2.5, while for the rest of the sample we used cooking fuel as a proxy for indoor PM2.5. Multivariable regression models adjusted for age, BMI, sex, smoking, cooking fuel, socio-economic status. Models were stratified by sex given the difference in residential time-activity reported for females. Result: A 10 µg/m<sup>3</sup> increase in ambient PM2.5 was significantly associated with a 0.8 mg/dl (95% CI: 0.5, 1.0) increase in HOMA-IR when adjusted for risk factors and cooking fuel. Cooking fuel type was not independently associated with HOMA-IR, but did have a significant interaction with ambient PM2.5, with higher effect on HOMA-IR in homes using solid fuels when compared to homes using LPG or a mix of fuels. A 10 µg/m<sup>3</sup> increase in indoor PM2.5 had a non-significant association with HOMA-IR in female participants (0.05 mg/dl [95%CI: -0.09, 0.19]), but no association in males. Conclusion: Ambient PM2.5 was positively associated with HOMA-IR in both males and females. Indoor PM2.5 and cooking with solid fuel was associated with HOMA-IR in females only.

## **P01.1210. Short-Term Association between Particulate Matter and Acute Atrial Fibrillation Episodes**

Marcus Dahlquist

*Marcus Dahlquist<sup>1</sup>, Leif Friberg<sup>2</sup>, Viveka Frykman-Kull<sup>2</sup>, Katrin Kemp Gudmundsdottir<sup>2</sup>, Emma Svennberg<sup>2</sup>, Gregory A. Wellenius<sup>3</sup>, Petter Ljungman<sup>1</sup>*

*2. Danderyd Hospital, Karolinska Institute, Stockholm, Sweden.*

*3. Brown University, Providence, RI, United States.*

**Abstract:** Introduction Atrial fibrillation (AF) is an arrhythmia prevalent in approximately 1-3 % of the population and is associated with a higher risk of stroke, dementia, and mortality, as well as reduced quality of life. Air pollution may be associated with heart rhythm disturbances, but there is limited evidence regarding whether short-term changes in air pollution levels are associated with acute onset of AF episodes. Methods Nearly 9,000 randomly selected 75-year olds living in Stockholm without previously known AF were screened for AF using short-term ambulatory 1 lead ECG-measurements 2-4 times a day for 14 days. Participants with AF at the index ECG did not undergo the rest of the measurements. Screenings were carried out in 2012-2014 and 2016-2018. We used generalized estimating equations to quantify the association between 24-hour exposure of Particulate Matter <10 µm (PM10) obtained from a fixed monitoring station and risk of AF onset in all participants with AF during the screening period, adjusting for temperature and temporal factors. Only AF episodes preceded by two consecutive recordings demonstrating sinus rhythm were included in the analysis. We explored potential susceptible subgroups and effect modifiers. Results Among 218 participants with 469 AF episodes we observed non-significant associations between PM10 and risk of AF [OR 1.07 (95% CI 0.94-1.21) per 10 µg/m<sup>3</sup>]. Statistically significant associations and stronger associations were observed among women (n=106) [OR 1.20 (95% CI 1.02-1.42) per 10 µg/m<sup>3</sup>] and for participants screened during the second screening period (n=95) [OR 1.26 (95% CI 1.06-1.50) per 10 µg/m<sup>3</sup>]. We did not observe effect modification by hypertension, ischemic heart disease or congestive heart failure. Conclusion Non-significant associations between short term increases in PM10 concentrations and acute episodes of atrial fibrillation were observed. The association was more pronounced and statically significant in women.

**P01.1220. Ambient Air Pollution in Relation to Diabetes and Hemoglobin A1c Biomarker in China: A Cross-Sectional Study with Findings from National Representative Data: WHO Study on Global Ageing and Adult Health (SAGE) Wave 1**

Mona Elbarbary

*Mona Elbarbary*<sup>1</sup>

*1. School of Public Health, The univeristy of sydney, NSW, NSW, Australia.*

**Abstract:** Background: Health effects of air pollution on diabetes have been scarcely studied in developing countries. We aimed to explore the associations of long-term exposure to ambient particulate matter (PM) and NO<sub>2</sub> with diabetes prevalence and hbA1C biomarker in China. Methods: we recruited 12,116 random participants aged over 50 years from 64 cities in China as part of the WHO Study on global AGEing and adult health (SAGE) wave 1 between 2007 and 2010. For respondents who provided consent (8660), blood sample was collected then analyzed diabetes (glycosylated haemoglobin and non-fasting random blood glucose). Diabetes was defined according to the American Diabetes Association's recommendations. We calculated exposure to air pollutants using data from monitoring stations (PM with an aerodynamic diameter of 10 µm or less [PM<sub>10</sub>] and nitrogen dioxide and a spatial statistical model (PM with an aerodynamic diameter of 1 µm or less [PM<sub>1</sub>] and 2.5 µm or less [PM<sub>2.5</sub>]). We used two-level logistic regression and linear regression analyses to assess associations between exposure and outcomes, controlling for confounders. Findings Most of the studied pollutants were significantly associated with increased diabetes prevalence (eg, the adjusted odds ratios associated with an increase in IQR for PM<sub>10</sub>, PM<sub>2.5</sub>, PM<sub>1</sub> and NO<sub>2</sub> were 2.05, 95% CI 1.20-3.50; 1.70, 1.01-2.87, 1.01, 0.77-1.32 and 1.25, 1.00-1.50 respectively). These air pollutants were also associated with higher concentrations of fasting glucose (0.03-0.07 mmol/L). Interpretation Long-term exposure to air pollution was associated with increased risk of diabetes in older adult Chinese population.

**Abstract:** Background: Exposure to air pollution during pregnancy may increase several behavior problems, including depression/anxiety or conduct/aggressive problems in children, but findings have been inconsistent. We aimed to study this association in a collaborative study of eight European predominantly urban population-based birth/child cohorts, including 13,376 mother-child pairs from thirteen geographic areas. Methods: Air pollution concentrations (nitrogen dioxide (NO<sub>2</sub>) and particulate matter) during pregnancy were estimated at the pregnancy addresses by land-use regression models based on monitoring campaigns performed between 2008 and 2011. Parents assessed depression/anxiety symptoms and conduct/aggressive problems at 8-12 years of age. We combined all adjusted area-specific effect estimates using random-effects meta-analysis and multiple imputation and applied inverse probability weighting methods to correct for loss to follow-up. Results: We classified a total of 1,625 children as having depression/anxiety symptoms within the borderline/clinical range and 855 within the clinical range, whereas 1,943 children were classified as having conduct/aggressive problems within the borderline/clinical range, and 861 within the clinical range. Exposure to air pollution during pregnancy was not associated with a higher odds of depression/anxiety symptoms within the borderline/clinical range (e.g., adjusted OR 0.98, 95%CI 0.95;1.02 per 10µg/m<sup>3</sup> increase in NO<sub>2</sub>) or with a higher odds of conduct/aggressive problems within the borderline/clinical range (e.g., adjusted OR 1.01, 95%CI 0.99;1.02 per 10µg/m<sup>3</sup> increase in NO<sub>2</sub>). We observed similar associations for the symptoms/problems within the clinical range. Low to moderate heterogeneity was found between areas. Conclusions: There was no evidence for an

increase in risk of depression/anxiety symptoms or of conduct/aggressive problems with increasing prenatal air pollution levels in children aged 8-12 years.

**P01.1240. Postnatal Exposure of PM10 and Autistic Behaviours among Children: The Mothers and Children's Environmental Health (MOCEH) Study**

**Abstract:** Background/Aim Environmental factors may play a role in the development of neurodevelopment and some studies have shown that ambient air pollution is associated with the autistic behaviours. The study was designed to investigate the impact of outdoor air pollution on autistic behaviours among children at 4, 5 years of age in Korea by using MOCEH cohort study's data. Methods This study is a part of the Mothers and Children's Environmental Health (MOCEH) study, a Korean multi-center prospective birth cohort study initiated in 2006. After delivery, children were followed up at 48 and 60 months of age. Average exposure level of particulate matter (PM10) were estimated using the inverse distance weighting (IDW) method from prenatal period to postnatal period. A total of 322 mother-child pairs were included. Autistic behaviours were assessed using the Social Responsiveness Scale (SRS) at 4, 5 years of age. We also examined the result stratified by sex of the children. Results The average levels of PM10 during pregnancy and 3 years of age were 54.07 $\mu\text{g}/\text{m}^3$  and 50.08 $\mu\text{g}/\text{m}^3$  each. In a multiple linear regression model, although we couldn't find significant positive relationship between exposure of PM10 in children, we found that PM10 at 3 years of age was associated with increased scores of SRS T-scores at 5 years of age in boys. ( $\beta=0.36$ , 95% confidence interval [CI]: 0.05,0.66) However, there was no significant positive association in girls. Conclusions In conclusions, postnatal exposure of PM10 is associated with the autistic behaviours, in boys at 4, 5 years of age. Further study on the other air pollutants effects to autistic behaviours in children is recommended.

## **P01.1250. Trimester-Specific Prenatal Exposure to PM2.5 and Birth Weight among Minority Populations in Puerto Rico**

Rafael Rios-McConnell

*Kipruto Kirwa<sup>2</sup>, Rafael E. Rios-McConnell<sup>1</sup>, Zaira Rosario<sup>1</sup>, Carmen Vélez-Vega<sup>1</sup>, Akram Alshawabkeh<sup>3</sup>, Jose Cordero<sup>4</sup>, Helen Suh<sup>5</sup>*

- 1. University of Puerto Rico Medical Science Campus, San Juan, PR, United States.*

- 3. Northeastern University, Boston, MA, United States.*
- 4. University of Georgia, Athens, GA, United States.*
- 5. Tufts University, Boston, MA, United States.*

**Abstract:** Background: While prenatal exposure to air pollutants has been associated with adverse birth outcomes, these associations are largely unstudied in minority populations. We assessed the association between trimester-specific maternal exposure to fine particulate matter (PM2.5) and birthweight (BW) in Puerto Rico for live births between 1999 and 2013. Methods: We studied 339,805 singleton births (mean gestational age: 37.9 weeks, SD: 2.9) to mothers whose mean age was 25.2 years (SD 6.0) in 37 Puerto Rican municipalities with at least 50% of their land area within 10 miles of a central regulatory air pollution monitor, from which we obtained daily PM2.5 concentrations. We included births for which gestational age was  $\geq 20$  weeks. PM2.5 exposure data were available for  $\geq 75\%$  of days in each trimester. We used a Poisson regression model with a sandwich linearized estimator of variance to estimate the association between mean exposure levels per trimester and BW, dichotomized as less than or  $\geq 2,500$  grams. We adjusted for individual and municipal-level confounders and allowed for potential clustering by municipality. Results: Median PM2.5 concentration across the study period was 7.0 micrograms/m<sup>3</sup> [interquartile range (IQR) 6.0-8.1], and 35,751 infants (10.5%) had low BW. Mothers attended  $\geq 10$  prenatal visits for 69.8% of births, 89.1% of them were Hispanic and 10.9% were black. The risk ratios associated with an IQR difference in PM2.5 concentration were 1.00 (95% CI 0.98, 1.02), 1.02 (1.00, 1.04), and 1.00 (0.98, 1.03) for trimesters 1, 2, and 3, respectively. Sensitivity analysis using ordinal logistic models that cast BW as very low, low, and normal yielded similar results: odds ratios 1.00 (0.98, 1.02), 1.02 (0.99, 1.04), and 1.01 (0.98, 1.04) for respective trimesters. Conclusion: Over 14 years in a population exposed to relatively low levels of PM2.5, second trimester exposures had the strongest association with low birth weight.

## **P01.1260. Ambient Air Pollution Exposure around Conception Increased the Risk of Miscarriage**

Zhongzheng Niu

*Zhongzheng Niu<sup>1</sup>, Jun Zhang<sup>2</sup>, Li Chu<sup>3</sup>, Yanjun Guo<sup>4</sup>, Lihua Qiao<sup>2</sup>, Meng Wang<sup>5</sup>, Zeinab Farhat<sup>1</sup>, Alexandra Grippo<sup>1</sup>, Lina Mu<sup>1</sup>*

*1. Department of epidemiology and environmental health, State University of New York at Buffalo, Buffalo, NY, United States.*

*3. Beijing Anzhen Hospital, Beijing, China.*

*4. Aerospace Center Hospital, Beijing, China.*

*5. Department of Environmental and Occupational Health Sciences, University of Washington, Seattle, WA, United States.*

**Abstract:** Introduction: The impact of ambient air pollution (AAP) exposure on miscarriage is unclear. This study aims to examine AAP exposure on the risk of miscarriage and to investigate the critical window of exposure. Methods: A total of 201 women in early pregnancy (4-6 weeks) were recruited in this prospective cohort from Beijing during May 2016 to May 2017, and 178 were followed during the second and the third trimesters, and at delivery. The participants provided residential and demographic information, disease history, health habits, and occupational exposures in the baseline survey. Events of miscarriage including spontaneous abortion and embryonic loss were self-reported during the follow-up periods. AAP including particulate matter 2.5 (PM2.5), nitrogen dioxide (NO<sub>2</sub>), and ozone (O<sub>3</sub>) from the 35 monitoring stations in Beijing were collected. Land Use Regression model estimated the participants' biweekly spatial AAP exposure from 8 weeks before conception till 20 weeks after. Log-binomial regression was used to assess the association of AAP exposure with the risk of miscarriage adjusted for parental age, maternal body mass index at baseline, and history of miscarriage or abortion. Results: A total of 22 (12.4%) participants reported miscarriage during 6-20 weeks of their pregnancy. AAP exposure varied across the time period with ranges of 20.9 - 207.6 ug/m<sup>3</sup> for PM2.5, 10.7 - 109.0 ug/m<sup>3</sup> for NO<sub>2</sub>, and 11.8 - 165.7 ug/m<sup>3</sup> for O<sub>3</sub>. The risk of miscarriage was about 4 times higher (risk ratio = 3.85, 95% confidence interval: 1.13 - 13.25) in women exposed to the highest tertile of PM2.5 (Median: 74.2, Interquartile range[IQR]: 35.81) compared to women exposed to the lowest tertile of PM2.5 (Median:55.87, IQR: 4.69) during the first two weeks of pregnancy. Risk of miscarriage was not significantly associated with AAP exposures during other periods. Conclusion: Exposure to high level of PM2.5 during the first two weeks of pregnancy may increase the risk of miscarriage.

**P01.1280. Seasonal Association between Ambient Ozone and Hospital Admission for Respiratory in Hanoi, Vietnam**

*4. International Laboratory for Air Quality & Health, Queensland University of Technology, Brisbane, QLD, Australia.*

**Abstract:** Background: While the level of air pollutants in Hanoi is frequently above the World Health Organization suggested level, few studies on the effects of ambient air pollution on health have been conducted in Vietnam. This study aimed to examine the effects of ozone on hospital admissions for respiratory diseases in Hanoi. Methods: Hospital admissions data were collected from three hospitals in Hanoi from January 2010 to June 2014. Air pollutants data were collected from Centre for Environmental Monitoring Portal for the same period of time. We used Generalized Linear Models and Distributed lag Linear Model to assess the association. We restricted analysis the data to two summer and winter season and grouped hospital admissions by diseases and ages. Results: Ozone was associated with the risk of admission for respiratory among group of children and all ages combined at lag 5 but not for older adults. For each increase of 10  $\mu\text{g}/\text{m}^3$  of ozone, the risk of admissions for respiratory disease at lag 5 increased 3.6% among children and 3.3% for all ages. The overall cumulative lag effects were statistically significant in both winter and summer. No significant association was found for wheeze-associated diseases in any age group. Conclusions: Ozone is a risk factor for respiratory admission, especially amongst children aged < 5 years old.

## **P01.1290. Comparative Assessment of Personal Exposure to Nitrogen Dioxide Using Land-Use Regression Modeling and Wearable Monitors**

Sarah Esenther

*Sarah E. Esenther<sup>1</sup>, Fareeha Irfan<sup>1</sup>, Elizabeth Lin<sup>1</sup>, Krystal J. Pollitt<sup>1</sup>*

Abstract: While measurements and models of ambient air pollutants are often used to determine the health risks and disease burdens of exposures, the cumbersome nature of exposure measurements have limited the exploration of the relationship between ambient pollutant concentrations and personal exposure. The development of the Fresh Air wristband, a wristband housing a passive NO<sub>2</sub> sampler, allows the personal exposure of vulnerable populations to be assessed directly to evaluate exposure ambient air pollutant concentrations. The objective of this study was to compare various methods for assessing personal exposure to NO<sub>2</sub> across a cohort of children in Springfield, MA. A sampling campaign was conducted during a winter season at 40 sites characterized by differing built environments and land uses. Nitrogen dioxide was measured at each site over a five-day period using a stationary Ogawa passive sampler. NO<sub>2</sub> exposure was estimated for 40 children (aged 12-13 years) using concentrations predicted using a land use regression model and measured directly using wearable samplers. The land use regression model was developed for the city of Springfield, MA (85 km<sup>2</sup> city area), and a validation of the land use regression model will be presented. Personal NO<sub>2</sub> was measured using Ogawa samplers that were housed in a Teflon chamber mounted in a wristband, worn by the children over a five-day period (Monday to Friday). A comparison of ambient NO<sub>2</sub> concentrations predicted using the land use regression model with wristband results will be discussed in relation to demographic characteristics and mode of transport to school.

## **P01.1310. Exposure to Pet or High-Level Outdoor PM2.5 in the First Year of Life and Risk of Atopic Dermatitis at 6 to 7 Years of Age**

Xue Han

*Xue Han<sup>1</sup>, Ho-Jang Kwon<sup>1</sup>, Ji-Ae Lim<sup>1</sup>*

*1. Department of Preventive Medicine, College of Medicine, Dankook University, Cheonan si, Korea (the Republic of).*

**Abstract:** Objective: The prevalence of non-infectious diseases, especially allergic diseases, have been increased in Korea. The aim of this study is to find out the association between exposure to pet or high-level outdoor PM2.5 in the first year of life and atopic dermatitis at 6 to 7 years of age in Korean children. Design and subjects: Based on the International Study of Asthma and Allergies in Childhood Study (ISAAC) in Korea (2010-2011), we analysed 848 1st grade elementary school students who had available data on ISAAC questionnaires in Seoul. To rule out genetic factors, we excluded children whose parents with atopic dermatitis from our studies. Atopic dermatitis was defined in a students who had self-reported symptoms or had treatment for atopic dermatitis within the last 12 months or diagnosis by physician in lifetime. Outdoor PM 2.5 concentration was obtained through the actual measurement. The association between exposure to pet or high-level PM2.5 during the first year of birth and atopic dermatitis was analyzed by using Multiple logistic regression. We used sex, age, breast-fed level as covariates in our model. Statistical analyses were performed using R .  
Results: Among 848 participants, 349(49.3%) were boys and 255 (30.1%) children turned out to be positive for atopic dermatitis. Forty one children (5.9%) were exposed to pet within the first year of life and 24-hour mean concentration of outdoor PM2.5 within the first year of life was 32.4µg/m<sup>3</sup> . In multiple logistic regression model, we found a significant association between pet exposure and high-level exposed to PM2.5 and atopic dermatitis after adjusting for covariates (the crude odds ratio (OR) =2.22, 95%CI:0.96 - 5.17, adjusted OR =2.47 95%CI: 1.01 - 6.08). Conclusion: We found a significant association between raising pets and exposed to high-level PM2.5 and atopic dermatitis in Korean children. Further longitudinal epidemiologic study will be needed to get more strong scientific evidence of this association.

**P01.1330. Effects of Air Quality Interventions on CLRD and IHD Mortality in Seoul, Korea.**

Sooyeon Kim

Sooyeon Kim<sup>2</sup>, Jong-Tae Lee<sup>1</sup>, Hyomi Kim<sup>2</sup>, Honghyok Kim<sup>2</sup>, Garam Byun<sup>2</sup>, Yongsoo Choi<sup>1</sup>, Hyeonjin Song<sup>1</sup>, Sera Kim<sup>2</sup>, Dahyun Baek<sup>2</sup>

1. School of Health Policy and Management, College of Health Science, Korea university, Seoul, Korea (the Republic of).

2. BK21PLUS Program in 'Embodiment: Health -Society Interaction', Department of Public Health Science, Graduate School, Korea university, Seoul, Korea (the Republic of).

**Abstract:** Background In 1990s and early 2000s, air quality interventions such as reinforcement of regulation of particulate matter (PM10) and sulfur dioxide (SO<sub>2</sub>) emission/air quality standards, supplement of low-emission cars and low sulfur fuel oil were conducted in Seoul, Korea. We assessed the effect of these air quality interventions on chronic lower respiratory diseases (CLRD) and ischemic heart diseases (IHD) mortality. Methods Concentrations of PM10 and SO<sub>2</sub> and directly age-standardized mortality of CLRD (ICD10 J40-J47) and IHD (ICD10 I20-I25) were compared between two periods (1998-2002, 2003-2007). We assessed the effect of interventions with an interrupted time-series analysis assuming Poisson distribution, adjusting for smoking, the quality of health care, and respiratory epidemics. Sex-specific age-standardized mortality were also estimated. Results Average PM10 concentrations decreased by 8.3% (5.6µg/m<sup>3</sup>), and SO<sub>2</sub> by 16.1% (0.001µg/m<sup>3</sup>) between the two periods. Adjusted CLRD mortality was reduced by 26.0% (95% CI: -1.7% to 46%), IHD mortality by 9.9% (95% CI: -2% to 18%). There was no significant difference in the mortality reductions for sex. Discussion Mortality reductions in chronic lower respiratory diseases and ischemic heart diseases in Seoul suggest that air quality interventions to control particulate air pollution could decrease mortality.

**P01.1340. Household Air Pollution, Ambient PM2.5 and Hypertension: Baseline Data from a Chinese Cohort Study**

Zhiguang Liu

Zhiguang Liu<sup>1</sup>, Tao Xue<sup>3</sup>, Lu Yin<sup>2</sup>, Hui Chen<sup>2</sup>, Lap Ah Tse<sup>1</sup>

1. *Environmental and Occupational health, JC School of Public Health and Primary Care, The Chinese University of Hong Kong, Hong Kong, SAR, Hong Kong, Hong Kong.*

3. *Dr. Qiang Zhang's Lab, Center for Earth System Science, Tsinghua University, Beijing, China, Beijing, China.*

Abstract: Few previous studies adequately considered the influences of household air pollution from various heating sources when investigating the association between hypertension and outdoor fine particulate matter (PM2.5). This study aims to address this identified research gap using baseline data collected from PURE-China. A total of 45108 participants aged 35 to 70 were recruited from 2005 to 2009. We estimate ambient PM2.5 concentration according to participants' household location. Household air pollution referred to the utilities of different primary heating sources during the cold or rainy season. Hypertension was defined as self-reported physician diagnosed or receiving BP treatment or the measurement of DBP  $\geq 90$  mmHg or SBP  $\geq 140$  mmHg at the interview. Multivariate logistic regression analyses were conducted to estimate the odds ratio and 95%CI with each 10 $\mu$ g/m<sup>3</sup> increment of PM2.5, after adjusting potential confounding factors. Further analyses were carried out according to three levels of household air pollution (i.e., unclean, clean, never using heating fuels). With each 10 $\mu$ g/m<sup>3</sup> increment of PM2.5, the OR for hypertension prevalence was 1.03(95%CI=1.04-1.14) according to the base model (i.e., adjustment of age, sex and region). After further including social economic status and disease history into the base model, the OR was 1.04(95%CI=1.02-1.06), and the effect retained almost unchanged if the household air pollution was included. Habitual use of unclean heating fuels significantly increased the risk of hypertension prevalence (OR=1.62, 95%CI=1.49-1.76, vs. clean ones). No excess risk was observed for those using the clean heating source (OR=0.96, 95%CI=0.86-1.07 vs. never using heating fuels). This study highlights that both outdoor PM2.5 and emissions from using heating fuels indoors are significant associated with increased risk of hypertension. There is a pressing need for global actions on removal the source of air pollution via particularly engineering control.

## **P01.1350. Near-Road Exposures to Traffic-Generated PM2.5, NOx and Black Carbon and the Risk of Daily Mortality: A Case-Crossover Study**

Paola Filigrana

*Paola A. Filigrana<sup>1</sup>, Chad Milando<sup>2</sup>, Stuart Batterman<sup>2</sup>, Adam Szpiro<sup>3</sup>, Sara Adar<sup>1</sup>*

*1. Epidemiology, University of Michigan, Ann Arbor, MI, United States.*

*2. Environmental Health Science, University of Michigan, Ann Arbor, MI, United States.*

*3. Biostatistics, University of Washington, Seattle, WA, United States.*

**Abstract:** Background: A large proportion of the US population lives and works near highways where levels of traffic-generated air pollutants are the highest. While these pollutants have been linked to adverse health, typical exposure estimates assume similar time trends across space and do not account for localized differences in traffic. Aim: We aimed to quantify associations between short-term variations in traffic-generated PM2.5, NOx and black carbon (BC) and non-accidental, cardiovascular (CVD) and respiratory mortality in near-road populations using finely resolved spatiotemporal traffic data. Methods: We conducted a time-stratified case-crossover study of non-accidental, CVD, and respiratory mortality among individuals living within 1 km of all highways in the Washington State Puget Sound. Leveraging highly resolved spatiotemporal traffic data (monitored each half-mile at 5-minutes intervals) and the Research Line source dispersion model (R-LINE), we predicted hourly concentrations of traffic-generated PM2.5, NOx and BC for each subject. We then ran conditional logistic regression models, adjusted for weather, holidays, influenza, and background PM2.5. Results: For each inter-quartile range increase in 24-hour average pollution levels, we found higher odds of respiratory mortality (PM2.5: OR: 1.01, 95%CI: 0.95-1.08, NOx: 1.02, 95%CI: 0.94-1.09, BC: 1.02, 95%CI: 0.96-1.08) and lower odds of cardiovascular mortality (PM2.5: OR: 0.97, 95%CI: 0.94-0.99; NOx: 0.96, 95%CI: 0.9-0.99, BC: 0.97, 95%CI: 0.94-1.00). For both outcomes and pollutants, we found stronger associations among residents within 300 m of a highway (PM2.5: 1.08, 95%CI: 0.98-1.19 for respiratory mortality and 0.95, 95%CI: 0.91-0.99 for cardiovascular mortality). No associations were found for non-accidental or stroke mortality. Conclusion: Short-term exposures to traffic-generated air pollution may influence the odds of mortality in near road populations, though not always in the expected direction.

**P01.1360. The Influence of Fine-Scale Spatiotemporal Variation of Traffic on Exposures to Traffic-Generated PM<sub>2.5</sub>, NO<sub>x</sub> and Black Carbon in Communities Located near Highways**

Paola Filigrana

*Paola A. Filigrana<sup>1</sup>, Chad Milando<sup>2</sup>, Stuart Batterman<sup>2</sup>, Sara Adar<sup>1</sup>*

*1. Epidemiology, University of Michigan, Ann Arbor, MI, United States.*

*2. Environmental Health Science, University of Michigan, Ann Arbor, MI, United States.*

**Abstract:** Background: Traffic varies dramatically by time and place, within and between highways. These variations likely influence the distribution of traffic-generated pollutants in nearby communities but this has not yet been well studied. Aim: We aimed to characterize the influence of spatiotemporal variations of traffic activity on traffic-generated PM<sub>2.5</sub>, NO<sub>x</sub> and black carbon (BC) in communities near highways. Methods: We leveraged traffic data available every ½ mile and 5 minutes for all highways in the Washington State Puget Sound (2009-2013) to estimate traffic-generated PM<sub>2.5</sub>, NO<sub>x</sub> and BC in nearby communities. First, we modeled hourly emission rates of PM<sub>2.5</sub>, NO<sub>x</sub> and BC for each road segment using the Motor Vehicle Emissions Simulator (MOVES). Then, we used the Research Line dispersion model (R-LINE) to predict hourly concentrations of traffic-generated PM<sub>2.5</sub>, NO<sub>x</sub> and BC at 9,829 subjects within 1 km from a highway. We aggregated modeled hourly concentrations to obtain 24-hour and annual average concentrations by pollutant. Results: Mean modeled concentrations of PM<sub>2.5</sub>, NO<sub>x</sub>, and BC generated by highway traffic were 1.6±2.2 µg/m<sup>3</sup>, 25.4±31.6 ppb, and 0.66±0.88 µg/m<sup>3</sup>, respectively. These values were highly variable over space and time with higher mean concentrations for receptors closer (<150 meters) to highways (PM<sub>2.5</sub>: 2.9±3.4 µg/m<sup>3</sup>, NO<sub>x</sub>: 44.8±48.9 ppb, BC: 1.2±1.4 µg/m<sup>3</sup>), and during morning rush hours (PM<sub>2.5</sub>: 3.1±2.5 µg/m<sup>3</sup>, NO<sub>x</sub>: 45.3±34.9 ppb, BC: 1.4±1.1 µg/m<sup>3</sup>). We also observed important spatiotemporal variability with evidence of larger between-day standard deviations (SD) for receptors <150 meters (PM<sub>2.5</sub> SD: 2.7 µg/m<sup>3</sup>, NO<sub>x</sub> SD: 37.7 ppb and BC SD: 1.1 µg/m<sup>3</sup>) as compared to receptors >150 meters of highways (PM<sub>2.5</sub> SD: 1.5, µg/m<sup>3</sup>, NO<sub>x</sub> SD: 21.9 ppb, BC SD: 0.61 µg/m<sup>3</sup>). Conclusions: This study shows that traffic air pollution from highways has strong patterns across time and space that cannot be captured by more conventional, aggregated metrics of exposure.

## **P01.1370. Studying the Effects of a Limestone Quarry on the Nearby Population's Exposure to PM**

Dana Drahler

*Dana Drahler<sup>1</sup>, Barak Fishbain<sup>1</sup>*

*1. Environmental engineering, Technion, Haifa, Israel.*

Abstract: The typical activity in a limestone quarry includes explosions, quarrying and passage of heavy duty-vehicles. These processes typically cause high rates particulate matter (PM) emissions. Therefore, quarries located in populated areas, may be an important cause of exposure to particulate air pollution. In order to quantify this phenomena, it is important to have a good understanding of the effects of quarries on ambient concentrations of PM. This study aims to characterize the particle emission and dispersion, caused by a limestone quarry, located about 500 meters from a populated area in central Israel. Since wind speed and direction has a great effect on the particle emission and dispersion, these two parameters were measured half-hourly measurements of solar radiation, ambient temperature and precipitation. Based on the results of the wind measurements, PM sensors were located at the expected hotspots. For control measurements, some sensors were located upwind, and next to the closest main road. The wind measurements were kept going during the PM measuring period as well. Spatiotemporal patterns of the measured PM fit well with our prior knowledge of local sources and their interactions with the meteorological parameters that were measured simultaneously. It seems that the population's exposure to PM depend heavily on the meteorological conditions and the geographic distance from the main sources, as well as the activity of these sources.

## **P01.1380. Indirect Personal Household Air Pollution Exposure Assessment for Children under 1 Year of Age Using Bluetooth Low Energy (BLE) Beacon System**

**Abstract:** Background: Household air pollution (HAP) generated from solid fuel combustion is associated with a large health burden in children under 1 year. However, assessing personal exposure to HAP for children is challenging, leading to uncertainties in estimating effects of a clean cookstove intervention program. Methods: We recruited 20 households cooking with open fires in Guatemala with women and children under 1 year and conducted two 24-hour PM<sub>2.5</sub> samplings before and two after a liquefied petroleum gas (LPG) stove intervention for each household. In each assessment, we measured 24-hour PM<sub>2.5</sub> levels in kitchens, sleeping rooms and outdoor patios as well as personal PM<sub>2.5</sub> exposure for 20 mothers using Enhanced Children's MicroPEM (ECM). We concurrently deployed a Bluetooth Low Energy (BLE) Beacon system to estimate the microenvironment location (kitchen, sleeping room and outdoor) for mothers and children longitudinally. PM<sub>2.5</sub> levels in the assigned microenvironments were used as indirect PM<sub>2.5</sub> estimates. We evaluated the performance of the Beacon system in predicting micro-environmental locations and personal PM<sub>2.5</sub> exposure. Results: Beacon system can predict microenvironment locations correctly over 70% of time, on average. After revising deployment strategies to reduce signal disturbance, this correct location rate increased to 80%. The mean of 24-hour Beacon-derived indirect nephelometric PM<sub>2.5</sub> exposure decreased from 110 µg/m<sup>3</sup> to 13 µg/m<sup>3</sup> for mothers and from 90 µg/m<sup>3</sup> to 9 µg/m<sup>3</sup> for children before and after the LPG intervention. The Spearman correlation coefficient between hourly indirect and direct personal PM<sub>2.5</sub> exposure for mothers was 0.92 before and 0.73 after LPG intervention. Conclusion: The BLE Beacon system can provide acceptable information of microenvironment location and estimate satisfactory personal PM<sub>2.5</sub> exposure in this LPG intervention pilot study. This novel exposure assessment method can be applied in future cookstove intervention studies.

## **P01.1381. Association of Indoor Air Pollutants and Cardiovascular Hemodynamics**

*1. Institute of Occupational Medicine and Industrial Hygiene, National Taiwan University, Taipei, Taiwan.*

*2. Department of Internal Medicine and Cardiovascular Center, National Taiwan University College of Medicine, Taipei, Taiwan.*

**Abstract:** Backgrounds: Indoor air quality has been associated with human health, however, there is limited information regarding personalized indoor air pollutants and cardiovascular hemodynamics. This study aims to investigate the concurrent real-time monitoring of indoor air quality and cardiovascular function. Methods: During July-October 2017, we recruited 40 subjects from 31 family for this study. Concurrent 24-h real-time monitoring of indoor air quality and cardiovascular hemodynamics were performed for each participant. Cardiovascular hemodynamics were measured via arterial pressure waveform by a cuff sphygmomanometer using an oscillometric BP device (DynaPulse 200M, Pulse Metric Inc., San Diego, CA). Time series analysis was applied to estimate the change of cardiovascular hemodynamics for every one unit (different scales) increase of air pollutants for 40 subjects. Results: The median (IQR) concentration of 24-hour indoor air pollutants were 28.80 (23.98)  $\mu\text{g}/\text{m}^3$  for PM<sub>2.5</sub>, 30.47(25.03)  $\mu\text{g}/\text{m}^3$  for PM<sub>10</sub>, 0.487(0.667)  $\mu\text{g}/\text{m}^3$  for carbon monoxide (CO), and 452.0 (295.0)  $\mu\text{g}/\text{m}^3$  for carbon dioxide (CO<sub>2</sub>). Time series analysis showed for every 1  $\mu\text{g}/\text{m}^3$  increase of indoor CO exposure, cardiovascular hemodynamics would increase 1.403(0.095-2.712) and 1.397(0.081-2.712) mmHg in concurrent and lag 1h systolic blood pressure respectively. In addition, the corresponding change of cardiac output would increase by 70 (13-127) ml and 73(14-132) ml for lag 1h and lag 4h respectively. For every 100  $\mu\text{g}/\text{m}^3$  increase in indoor CO<sub>2</sub> exposure, the concurrent and lag 1h cardiac output would increase by 24.1(4.9-43.3) ml and 31(12.8-49.2) ml respectively. Conclusion: Real-time indoor air quality monitoring of CO and CO<sub>2</sub> was strongly associated with personalized 24h cardiovascular hemodynamics.

**P01.1390. Multiscale Modeling of Human Exposure to Traffic Related Air Pollution: Focus on New Jersey Industrial/Transportation Corridor**

Zhongyuan Mi

*1. Environmental and Occupational Health Sciences Institute, Rutgers University, Piscataway, NJ, United States.*

Abstract: The New Jersey Industrial/Transportation Corridor (NJITC), connecting New York, NY; Newark, NJ; and Philadelphia, PA, is one of the busiest road networks in the world. Exposure to Traffic Related Air Pollution (TRAP) is an important health concern for people living and/or commuting within this area. A multiscale/multi-model simulation approach, utilizing observations, CMAQ (the Community Multiscale Air Quality model) and RLINE (the Research LINE-source dispersion model) is used to estimate the spatiotemporal distribution of NO<sub>x</sub> and diesel exhaust particles from on-road automobiles sources. The road network, traffic volumes and fleet composition were obtained from the Highway Performance Monitoring System (HPMS), New Jersey Department of Transportation (NJDOT) and emission factors were extracted from the MOtor Vehicle Emission Simulator (MOVES2014a). Bayesian data fusion was used to adjust model estimates employing observations from local ambient air monitoring stations. The present study utilizes information collected through the earlier Rutgers Commuter Community Cohort (RC3) study, including databases of spatio-temporal commuting trajectories and associated measured personal in-vehicle concentration profiles. The Spatio-Temporal Information System (RC3-STIS) developed for the RC3 study to provide data management, analysis, visualization and screening exposure modeling capabilities, is being utilized and extended for the present study. It is coupled with the CMAQ/RLINE simulation output, a route option optimizer (developed with Google Map API) and the Agent-Based Model of Human Exposures (ABM-HE) module within the PRoTEGE (Prioritization and Ranking of Toxic Exposures with GIS Extension) system, to support further analyses of commuting behavior and of associated exposures, under scenarios that extend beyond the situations assessed and data collected via the RC3 study.

## **P01.1400. Spatiotemporal Trends in Air Pollution and the Built Environment in Urban Areas in Chile 2002-2015**

Raquel Jimenez Celsi

*Raquel B. Jimenez Celsi<sup>1</sup>, M. Patricia Fabian<sup>1</sup>, Kevin J. Lane<sup>1</sup>*

*1. Environmental Health, Boston University, Cambridge, MA, United States.*

Abstract: Chile has undergone rapid urbanization during a three-decade period of sustained development, resulting in increased air pollution in urban areas. In developed countries, health effects of air pollution have been shown to be modified by the built environment, but few studies have been conducted in South American cities due to lack of data. Remote sensing is an underused global resource that can be used to characterize air pollution and the built environment in countries such as Chile. We performed a spatiotemporal analysis of PM<sub>2.5</sub>, greenness, nighttime lights (NTL) trends in 493 urban areas in Chile from 2002 to 2015. We used annual mean PM<sub>2.5</sub> estimates developed for the Global Burden of Disease at 1 km<sup>2</sup> resolution. Greenness was assessed using Moderate Resolution Imaging Spectroradiometer derived Normalized Difference Vegetation Index (NDVI) at 250 m<sup>2</sup> and 16-day resolution. Visible Infrared Imaging Radiometer Suite derived NTL at 500 m<sup>2</sup> and 30-day resolution was used to measure urbanization density. We compared changes in PM<sub>2.5</sub>, NDVI and NTL across the 13-year period in urban areas of Chile. We also stratified by geographical region into north, central and south zones. Annual average PM<sub>2.5</sub> and NTL increased by 10.8% (1.23 µg/m<sup>3</sup>) and 24%, respectively over the study period, while NDVI decreased by 4.2%. PM<sub>2.5</sub> and NTL were positively correlated ( $r = 0.66$ ;  $p < 0.001$ ); while NDVI was inversely correlated with PM<sub>2.5</sub> ( $r = -0.44$ ;  $p < 0.001$ ) and NTL ( $r = -0.58$ ;  $p < 0.01$ ). We found differential change rates over time by geographical region, with urban areas in the central zone having the most pronounced increases in PM<sub>2.5</sub> and NTL and fastest decrease in NDVI compared to north and south zones. We generated built environment data for urban areas in Chile using public satellite data, applying methods that can be replicated in any country. The PM<sub>2.5</sub>, greenness, and NTL databases generated are a valuable resource that can be used in urbanization studies and air pollution epidemiology.

## **P01.1420. Dust Collection Efficiency by Installing the Dust Screen in Houses**

Juri Shim

*Juri Shim<sup>1</sup>, Soyoeng Byeon<sup>1</sup>, Sunshin Kim<sup>2</sup>, Hyeon-Su Ryu<sup>1</sup>, Jinhyeon Park<sup>1</sup>, Wonho Yang<sup>1</sup>*

*1. Occupational Health, Catholic University of Daegu, Dae-gu, Korea (the Republic of).*

*2. Environmental Health Center, Soonchunhyang University Gumi Hospital, Gyeongbuk, Korea (the Republic of).*

**Abstract:** Humans have a desire to inhale the fresh outdoor air even indoor air quality is satisfactory. When the window is opened to ventilate, air quality satisfaction maybe higher than closed even the not cleaned air is entered. The purpose of this study was to evaluate indoor air quality improvement by measuring dust collection efficiency and ventilation rate reduction by installing the dust screen. Dust screen was made by modification of insect-proof net and can collect the dust by electromagnetic force. The dust collection efficiency was performed at the laboratory level and houses. The static pressure difference and flow velocity, and PM10 concentration by direct-reading instruments were measured to compare the variation of the dust collection efficiency and the ventilation rate. The static pressure difference was 0.3 mmH<sub>2</sub>O, and the concentration of PM10 concentration was decreased by 5.81% in insect-proof net. On the other hand, when dust screens were installed, the flow velocity was reduced by 20% and the static pressure difference was 1.3 mmH<sub>2</sub>O. And the dust collection efficiency of dust screen was 74.4%. It was confirmed that the ventilation rate was reduced to about 1/4 level when the dust screen was installed. Consequently, the pressure loss due to the insect screen and dust screen was 1.0 mmH<sub>2</sub>O and 2.7 mmH<sub>2</sub>O. Also, the dust collecting efficiencies of insect-proof net and dust screen was 12.9% and 74.4% respectively. In conclusion from a health perspective, efforts should be made to reduce exposure to fine dust in the atmosphere such as installation of a dust screen.

## **P01.1430. Quantifying PM2.5 Exposure from Residential Source According to Fuel Uses in Highly Polluted Ambient Environment**

Hanbin Zhang

*Hanbin Zhang<sup>1</sup>, Yunfei Fan<sup>2</sup>, Yiqun Han<sup>1</sup>, Li Yan<sup>1</sup>, Yutong Cai<sup>3</sup>, Bingling Zhou<sup>1</sup>, Wu Chen<sup>2</sup>, Queenie Chan<sup>3</sup>, Tong Zhu<sup>2</sup>, Frank Kelly<sup>1</sup>, Benjamin Barratt<sup>1</sup>*

*1. Environmental Research Group, MRC PHE Centre for Environment and Health, King's College London, London, United Kingdom.*

*3. Department of Epidemiology and Biostatistics, MRC PHE Centre for Environment and Health, Imperial College London, London, United Kingdom.*

**Abstract:** Background Many studies have reported residential PM2.5 concentrations in association with fuel uses. Yet it remains a challenge to identify and quantify PM2.5 from residential sources in real-time exposure datasets. Censoring algorithms, which were usually used in infiltration factor calculation, could be useful for this exercise. Methods Thirty-seven senior non-smoker participants in an urban or a rural site of Beijing have completed residential exposure monitoring for at least 43 hours, during Nov-Dec 2016 (winter) and May-Jun 2017 (summer). Residential PM2.5 was measured in subjects' bedrooms using nephelometers. Corresponding outdoor PM2.5 concentrations were measured by reference monitors. A censoring algorithm (Allen et al., 2003) was applied to select data points when a residential source of pollution was identified. The ratios between residential and outdoor (R/O ratio) PM2.5 for these subjects were compared according to their fuel use information. Results In summer, subjects who used biomass for cooking have significantly higher average R/O ratio to PM2.5 than those who used non-biomass ( $p < 0.05$ ). Mean (standard deviation [SD]) R/O ratio during summer for biomass and non-biomass users were 1.5(0.5) and 1.1(1.0). The mean (SD) residential PM2.5 concentrations during summer for biomass and non-biomass users were 49.7(34.7) and 36.7(21.4)  $\mu\text{g}/\text{m}^3$ . In winter, subjects who used solid fuel (biomass or coal) for heating have significantly higher average R/O ratio to PM2.5 than those who used alternative energy (electricity or central heating) ( $p < 0.05$ ). Mean (SD) R/O ratio during winter for solid fuel and alternative energy users were 3.2(3.6) and 1.6(1.1). The mean (SD) residential PM2.5 concentrations during winter for solid fuel and alternative energy users were 315.7(313.4) and 147.8(52.2)  $\mu\text{g}/\text{m}^3$ . Conclusions Censoring algorithms from infiltration studies can be effective in quantifying residential source of pollution, even in highly polluted ambient environments.

## **P01.1440. Household Air Pollution and Urine Metabolomics in Tibet**

Teng Wang

*Teng Wang<sup>1</sup>, Wenlu Ye<sup>2</sup>, Saikawa Eri<sup>2</sup>, Tong Zhu<sup>1</sup>*

*1. SKL-ESPC and BIC-ESAT, College of Environmental Sciences and Engineering, Peking University, Beijing, Beijing, China.*

*2. Department of Environmental Health, Emory University, Atlanta, GA, United States.*

**Abstract:** Background:Evidences show that exposure to air pollution is associated with a number of adverse health outcomes. Household air pollution (HAP) from solid fuel burning is one of the most important risk factors, especially in developing countries. As part of the southwest region in China, Tibetan plateau is a pristine area with clean air quality, hence is an idea place to study the health effects of household air pollution. Method:This project addressed HAP and health issues in China by measuring personal exposure to PM<sub>2.5</sub> (n=46) and kitchen area BC concentrations (n = 8), and conducting urine metabolic profiles collected from 46 Tibetans living in three villages with ultrahigh performance liquid chromatography-mass spectrometry. Household energy use surveys (n=24) were conducted regarding demographics, cook stove usage, household fuel, cooking behaviors and life styles. Results:More than 4000 metabolites were obtained from the urine samples which were existing in each subject. In hierarchical cluster analysis, we found two principle hierarchies associated with two typical sub-populations. The metabolic profiling of these two sub-populations is correlated with villages, whereas no correlation with age and gender was found. When samples were grouped by villages, PCA analysis shows principal component one could explain close to 44% of the sample variations. Besides, around 400 unique metabolites were found in village 2. Conclusion: Urine sample analysis show that the two groups have distinctly different metabolic profiles, and this might be associated with different exposure environment. Analysis using factors such as fuels, stoves, activity that could possibly affect health effects will be conducted. Further analysis could be performed to study the association between HAP exposure and various health endpoints, with the metabolites in urine samples, such as PAHs, providing profiling for stratified analysis as well as for possible illustration of the health effects pathways.

**P01.1450. Association of Morning Distribution of Real-Time Indoor Ultrafine Particulate Matter (PM2.5) Concentrations with Daily Activity Patterns of Asthmatics in South Korea : Preliminary Study Results**

Sujung Park

*Sujung Park<sup>1</sup>, Juhee Kim<sup>1</sup>, ChoonSik Park<sup>2</sup>, Daehyeon Lim<sup>3</sup>, Sungroul Kim<sup>1</sup>*

- 1. Department of Environmental Sciences, Soonchunhyang University, Asan, Korea (the Republic of).*
- 2. Department of Internal Medicine, Soonchunhyang Bucheon Hospital, Bucheon, Korea (the Republic of).*
- 3. Inha University hospital, Incheon, Korea (the Republic of).*

Abstract: Asthmatics may be more susceptible to ultrafine particulate matter (PM2.5), due to its large number of chemicals attached on it, compared to ordinary population. Acute exacerbations of RA can lead to such severe airway obstruction that mechanical ventilation is required as a lifesaving measure. Thus, knowing the risk factors for RA is important for minimizing both the need for emergency medical interventions and disruption of daily activities. And depending on patients' degree of symptoms, acute exposure to PM2.5 can lead to severe airway obstruction. Indoor PM2.5 may be the mixture of the influx of outside air and indoor activities. Thus, understanding of the association of indoor activity pattern and variation of indoor PM2.5 level is important. The purpose of this study was to obtain the distribution of hourly indoor PM2.5 concentration in asthmatics' houses, and to evaluate its association with their daily activity pattern. From November 2016 to November 2017, a real-time PM2.5 concentrations were measured at the livingroom of each asthmatic's house (n=30) for 3 weeks with 1 minute intervals. At the same time, self-reported daily activity patterns, i.e., hourly proportion(%) of cooking activities, were also recorded every hour over 3 weeks for each patient. The median concentration of PM2.5 at the morning cooking time (7:00 to 10:00 am) was 30.0 ug/m<sup>3</sup>. The distribution pattern of hourly proportion of cooking activities were similar to that of PM2.5 concentration level, but there was 1 or 2 hour time lag. Spearman correlation coefficient between the hourly proportion of cooking activities and the PM2.5 concentration was 0.67 and 0.65 (p=0.072 and 0.078) at child asthmatics' houses and 0.7 and 0.87 (p=0.233 and 0.058 for 8 O'clock and 9 O'clock) at adult asthmatics' houses. Our real-time monitoring results demonstrated that variation of indoor morning PM2.5 concentration level was potentially associated with indoor cooking activity patterns at home.

## **P01.1460. Estimation of Ventilation Rate in Houses Using Time-Activity Pattern and Indoor Carbon Dioxide Concentration**

Soyoeng Byeon

*Soyoeng Byeon<sup>1</sup>, Sunshin Kim<sup>2</sup>, Hyeon-Su Ryu<sup>1</sup>, Jinhyeon Park<sup>1</sup>, Juri Shim<sup>1</sup>, Wonho Yang<sup>1</sup>*

*1. Daegu Catholic University, Daegu, Korea (the Republic of).*

*2. Environmental Health Center, Soonchunhyang University Gumi Hospital, Gyeongbuk, Korea (the Republic of).*

Abstract: Since most people spend more than about 90% of the day in indoor environments, indoor air quality is a major setting for assessing exposure to air pollutants. Factors affecting indoor air quality are indoor pollutant generation, ventilation rate, pollutant decay rate, indoor air mixing degree, outdoor pollutant concentration and indoor space volume. Among them, the ventilation rate has many limitations on the direct measurement. Therefore, it is hard to provide a representative value. The purpose of this study suggests the average ventilation rate of Korean houses using time-activity pattern and indoor carbon dioxide (CO<sub>2</sub>) concentration. Indoor air quality model was used with the hourly indoor CO<sub>2</sub> concentration of 7,500 houses during 11 months in 2015 using sensor measurements and the time-activity pattern using data from the 2014 Time-Use Survey of about 28,000 people accessed from the Korea National Statistical Office. The CO<sub>2</sub> emission per capita in the house was assumed to be 0.22 ~ 0.33 L / min based on the previous reports. The outdoor CO<sub>2</sub> was assumed to be 400 ppm and the average volume of the house was 97.4 m<sup>3</sup> according to Statistics Korea. Using a mass balance model, the ventilation rate was calculated. Using time-activity patterns of Koreans and indoor CO<sub>2</sub> concentrations in houses, the calculated average air exchange rate was 0.56±0.14 ACH (air exchange per hour) in Korea houses. Indoor air quality can be affected by indoor sources, ventilation, decay and outdoor levels. Although technologies exist to measure these factors, direct measurement are often difficult. Specially, the ventilation rate was needed considering the outdoor contribution to house indoor. In this study, using mass balance model with measure CO<sub>2</sub> concentrations in house indoors and time-activity pattern of Koreans, the ventilation rate was estimated. The estimated average ventilation rate in houses of Korea was considered to be representative value.

**P01.1470. Indoor Air Pollutants Exposure and Determinant Factors Controlling Households Air Quality for Elderly People in Hong Kong**

Xinning Tong

*Xinning Tong<sup>1</sup>, Kin-Fai Ho<sup>1</sup>*

*1. School of Public Health, The Chinese University of Hong Kong, Hong Kong, China.*

**Abstract:** This study investigated the levels and determinant factors of indoor air pollutants including fine particles (PM<sub>2.5</sub>), nitrogen dioxide (NO<sub>2</sub>) and formaldehyde in 55 households exclusively for elderly at Hong Kong during summer and winter (Jul.- Sep. 2016 & Nov. 2016 - Mar. 2017). The average concentrations of PM<sub>2.5</sub>, NO<sub>2</sub> and formaldehyde were 25.3+15.0 µg/m<sup>3</sup>, 40.5+16.0 µg/m<sup>3</sup> and 26.1+22.8 µg/m<sup>3</sup> in summer; 34.2+19.0 µg/m<sup>3</sup>, 43.5+17.0 µg/m<sup>3</sup> and 15.4+4.5 µg/m<sup>3</sup> in winter, respectively. There were ~50.3% households exceeding the World Health Organization indoor air quality standard for PM<sub>2.5</sub> throughout the study, with ~40.6% and ~61.0% households in summer and winter, respectively. The determinant factors for indoor PM<sub>2.5</sub> and NO<sub>2</sub> concentrations were identified as from incense burning and cooking source. Cooking with suitable ventilation is an important factor to ease indoor pollutants concentrations. Both of PM<sub>2.5</sub> and NO<sub>2</sub> indoor concentrations showed good correlations with outdoor concentrations. Winter was observed with higher pollutants concentrations than summer except for formaldehyde concentrations. Major factors controlling indoor formaldehyde concentrations are temperature and humidity. The outcome will be useful for future indoor air quality guidelines development in Hong Kong.

## **P01.1480. Particle Generation Analysis of Squalene-Ozone Reactions**

Breann Coffaro

*Breann Coffaro<sup>1</sup>, Clifford Weisel<sup>1</sup>*

*1. Exposure Science, Rutgers, Highland Park, NJ, United States.*

Abstract: Humans are continuously exposed to ozone and its by-products through ambient ozone penetration indoors. Both volatile and particulate phase by-products have been found inside homes due to the reaction of ozone with highly reactive squalene, a natural component of skin oil. Particulate phase by-products may cause respiratory and ocular irritation due to their common chemical makeup consisting of carbonyls and organic acids. This work investigates the effect of varying concentrations of ozone, squalene, reaction duration, and humidity levels on both particle number generation and particle size. Squalene was loaded onto a surface at varying concentrations of 0.25-0.76 mg/cm<sup>2</sup> and ozone was passed over the surface at concentrations between 100-700 ppb to initiate the reaction. Produced particles were analyzed with a TSI Condensation Particle Counter, a Grimm mini-WRAS aerosol spectrometer, and collected on Teflon filters for extraction and derivatization with BSTFA. Subsequent analysis and identification by GC-MS were conducted where succinic acid and levulinic acid were identified as the likely unique squalene-ozone reaction products, as well as nine other alcohols and carboxylic acids. Particles produced from pure squalene are compared to that of total skin oil and those found in an air sample collected from inside a home. Particles were found to form approximately one hour after the introduction of ozone and found to be related to the relative humidity, which is consistent with nucleation and condensation mechanisms. Given the aforementioned squalene and ozone concentrations, particle counts ranged from 200-6000 #/cc The presented work aims to investigate a reaction taking place on the surface of the skin and identify compounds people may be exposed to inside their home.

## **P01.1490. Effects of Environmental Factors on Sampling Rates of VOCs with Porous Tube-Type Passive Samplers**

Haruna Nishio

*Haruna Nishio<sup>1</sup>, Qi Wang<sup>1</sup>, Masahiro Tokumura<sup>1</sup>, Yuichi Miyake<sup>1</sup>, Takashi Amagai<sup>1</sup>, Yasuhiro Fukushima<sup>2</sup>, Yoshihiro Suzuki<sup>2</sup>, Takanori Enomoto<sup>2</sup>*

- 2. Sibata Scientific Technology, Saitama, Japan.*

**Abstract:** Aim: It was reported that some volatile organic compounds (VOCs) caused occupational cancers. It is necessary to measure the accurate concentrations of VOCs for preventing diseases. Although passive sampling methods for measuring VOCs are useful, they may not be accurate because sampling rates of VOCs with passive samplers are affected by various environmental factors. Our aim was to reveal the effects of environmental factors on the sampling rates. Methods: Five conditions (run 1-5) in chamber (diameter, 0.12 m; length, 5.7 m) were set according to the ISO 16107 method. Ten VOCs including cyclohexanone were selected in this study. Temperature, humidity, wind speed and VOCs concentration in the chamber were controlled and monitored in real time in order to check the accuracy and variation of conditions inside the chamber. Prior to the sampling, the conditions in the chamber were kept for about one hour, and VOCs were collected for four hours with active samplers and passive porous tube-type samplers (Carbon beads passive: CBP or Charcoal passive: PAS), simultaneously. The samples were extracted with 2 mL of carbon disulfide, and the solutions were then filtrated and analyzed by GC/MS. Results: There were no significant differences in sampling rates of each conditions for CBP or PAS. For example, results of cyclohexanone in run 1 (temperature: 25°C, humidity: 80%, wind speed: 0.1 m/s, VOCs injection rate into chamber: 10 µg/min) were as follows: CBP;  $0.215 \pm 0.010$  µg/ppmv/min, PAS;  $0.196 \pm 0.010$  µg/ppmv/min. The averages sampling rates of cyclohexanone in run 1 to run 5 were as follows: CBP;  $0.210 \pm 0.012$  µg/ppmv/min, PAS;  $0.206 \pm 0.019$  µg/ppmv/min. Conclusion: We found that sampling rates of cyclohexanone with porous tube-type passive samples were constant under the different environmental conditions operated in this study.

## **P01.1491. Examining the Relationship between Household Air Pollution and Infant Nasal Carriage**

Daniel Carrion

*Daniel Carrion<sup>1</sup>, Kenneth Asayah<sup>2</sup>, Ellen Boamah<sup>2</sup>, Mohammed Mujtaba<sup>2</sup>, Alison Lee<sup>3</sup>, Kaali Seyram<sup>2</sup>, Darby Jack<sup>1</sup>, Kwaku Poku Asante<sup>2</sup>*

**Abstract:** Background/Aim: Pneumonia, the leading cause of childhood mortality worldwide, is associated with household air pollution (HAP) exposure. Mechanisms between HAP and pneumonia are poorly understood, but the Randomized Exposure Study of Pollution Indoors and Respiratory Effects trial in Guatemala identified severe pneumonia as more likely of bacterial, rather than viral, etiology. Our research seeks to confirm relationships between HAP and infant bacterial carriage, specifically among those diagnosed with pneumonia. Methods: Data were collected through the Ghana Randomized Air Pollution Study (GRAPHS), which recruited mother-infant pairs until the child's first birthday. Improved biomass, LPG, or 3-stone (baseline) cookstoves were randomly assigned to participants. The current analysis is restricted to LPG and 3-stone arms. Carbon monoxide (CO) exposures were measured for each infant and fieldworkers conducted surveillance for pneumonia. Cases were sent for treatment and nasopharyngeal swabs. Age and sex-matched controls were swabbed. Swabs were analysed with MassTag PCR for common infections. Statistical analyses included group-wise comparisons of microbial pathogens by study arm. At study completion, the association between CO-levels and specific microbes will be analysed. Results: Preliminary analysis demonstrates participants in the 3-stone arm have higher microbial levels than the LPG intervention arm ( $p < 0.0001$ ) ( $N = 198$ ). This difference appears driven by bacterial ( $p < 0.0001$ ) rather than viral levels (non-significant) among 3-stone participants. Bacterial-level differences are consistent when stratifying by cases ( $p < 0.0001$ ) and controls ( $p = 0.0049$ ). Forthcoming analysis will assess the effects on specific microbe species. Conclusions: Findings could strengthen knowledge of pneumonia etiology. Childhood pneumonia is a grave public health concern and these data could inform public health efforts, including HAP interventions or vaccination programs.

## **P01.1492. Environmental Interventions in Primary Schools and Its Impacts on Indoor Air Quality and Student Health**

**Abstract:** Background: Deficient indoor environmental quality (IEQ) in schools could adversely affect the performance and physical health of students and teachers. Ventilation rate and particle filtration are two key factors that influence IEQ. Aims: We present the design and selected results of an intervention study conducted in two schools with 2nd to 4th grade students. We describe a number of innovative outcome measures for both academic performance and physical fitness.

**Methods:** We conducted a blinded case-crossover trial of two interventions, increased ventilation rates and advanced particle filtration, in two primary schools. The school year was divided into five periods; a baseline period and four intervention periods, during which one-half of the classrooms was the treatment group; the other half was not. In each period, we measured IEQ parameters, e.g., optical particle counts (OPC), particulate matter (PM) concentrations, air change rates, volatile organic compounds (VOCs), in four classrooms in each school. Outcome measures, obtained on 629 students, included absenteeism, curriculum-based tests in several academic areas, and the progressive aerobic capacity endurance run (PACER) tests, which measures the cardio-respiratory endurance/aerobic capacity. **Results:** Interventions altered PM concentrations but did not appear substantially change estimated ventilation rates. We found that the PACER fitness scores varied little between treatment and control groups across intervention periods, but longitudinal analyses showed several changes. The interventions did not appear to alter absenteeism. Results for the two schools differed, possibly reflecting the ability to successfully implement interventions. **Conclusions:** The study suggests the potential of intervention studies in schools for identifying strategies that benefit indoor air quality and students' physical health, and suggests the need to control for time varying factors that may influence outcomes.

**P01.1493. Associations of PM2.5 Source Concentrations with Childhood Asthma Emergency Department Visits in the U.S. State of Georgia: A Case-Crossover Study**

Mengjiao Huang

*Mengjiao Huang<sup>1</sup>, Cesunica Ivey<sup>2</sup>, Yongtao Hu<sup>3</sup>, Heather Holmes<sup>4</sup>, Matthew Strickland<sup>1</sup>*

- 2. Chemical and Environmental Engineering, University of California, Riverside, CA, United States.*
- 3. School of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, GA, United States.*
- 4. Department of Physics, Univeristy of Nevada, Reno, NV, United States.*

**Abstract:** Background A novel hybrid air quality model that provides complete spatial coverage of PM2.5 source concentrations throughout the U.S. State of Georgia was used to investigate associations of air pollution sources with childhood asthma exacerbations. Objectives Estimate and compare associations of 12 PM2.5 source concentrations (i.e., contributions of emissions from motor vehicles, power plants, etc. on PM2.5 concentrations) with childhood asthma Emergency Department (ED) visits. Methods ED visits for asthma or wheezing (N=122,414) among children and adolescents (age ≤18 years) were obtained from patient claims records (in 2005 and 2007). Daily average PM2.5 concentrations from 12 sources were estimated using a hybrid chemical transport (CTM)-receptor model fused with observations from stationary monitors. In the case-crossover study, odds ratios for 3-day moving average PM2.5 concentrations were estimated using conditional logistic regression, matching on day-of-week and month, and adjusting for average temperature (3-day moving average), water vapor mixing ratio (3-day moving average), and Federal holidays. Results We observed positive associations between several PM2.5 sources and asthma ED visits. For example, per interquartile range increase in the source contribution, odds ratio estimates were 1.014 (95% CI: 1.008, 1.020) for dust; 1.029 (95% CI: 1.020, 1.039) for metals, and 1.044 (95% CI: 1.027, 1.063) for natural gas. These sources comprise 5.2%, 2.2%, and 6.5% of total PM2.5 mass, respectively. Heterogeneity in odds ratios across sources could reflect differences in the importance of sources in triggering asthma exacerbations. Because the CTM has uncertainties in the emissions and meteorology inputs and in the modeling of atmospheric processes, such conclusions are tentative. Conclusions Short-term increases in the concentrations of PM2.5 from several sources were associated with increases in childhood asthma ED visits.

**P01.1494. Using Measurements of Nitrogen Oxides from a Fixed Site and a Mobile Platform to Develop Spatially- and Temporally-Resolved Land Use Regression Models**

**Abstract:** Background: Land use regression models can have limited temporal representativeness or spatial resolution if mobile monitoring or fixed site data are used exclusively. Our objective was to build hourly spatial and temporal nitrogen oxides (NO<sub>x</sub>) models for 2003-2015 in Boston and Chelsea (MA, USA) by combining measurements from a mobile platform and a fixed reference site.

**Methods:** NO<sub>x</sub> measurements were made with a chemiluminescence analyzer mounted in a mobile platform. Monitoring sessions (3-6 hours long) occurred on 49 days in Boston and 46 days in Chelsea between 2011 and 2015. Sessions occurred on all days of the week and in all seasons. We obtained hourly NO<sub>x</sub> measurements from a federal monitoring site in Boston. We calculated spatial factors, defined as the location-specific ratio between each 10-second mobile NO<sub>x</sub> value and the corresponding hourly mean fixed site NO<sub>x</sub> value. To model the spatial factors, we tested 43 covariates including transportation network and land use variables with data obtained from public sources. We prioritized covariates that most increased the adjusted-R<sup>2</sup> and made physical sense. We multiplied the modeled spatial factors by the fixed site hourly mean to estimate NO<sub>x</sub> at <200-m and 1-h resolution. **Results:** The models were stable with two cross validation methods. The most important predictors were distance from major roads, open space, and residential areas; presence of bus/train stops; and an interaction term for wind speed and being downwind of an airport. The models over-predicted at three validation sites, especially when concentrations were low and in places farther from major roads; however, the adjusted-R<sup>2</sup> values for hourly predictions were high (0.53-0.62) and the model captured seasonal and diurnal trends well for both study areas for 2003-2015. **Conclusion:** Our modeling approach is an efficient way to develop spatially and temporally resolved exposure estimates for use in concurrent and retrospective epidemiology studies.

## **P01.1500. Acute Associations between PM2.5 and Allergic and Nonallergic Asthma Exacerbations in Children and Adults**

Natalie Rosenquist

**Abstract:** Introduction: Asthma results from airway inflammation and has allergic and nonallergic phenotypes. It is unknown whether susceptibility to the acute effects of air pollution differs by asthma phenotype. Methods: Associations of ambient PM2.5 concentrations with acute asthma visits (including unscheduled office, urgent care, emergency department, and hospitalization) were investigated using electronic medical records from Renown Health in Reno, the largest healthcare network in Northern Nevada. International Classification of Disease (ICD) codes were used to identify patients with at least one asthma visit (N=23,331), and to classify asthma patients by phenotype based on the presence or absence of an allergic comorbidity (atopic dermatitis, allergic rhinitis, or allergy) in their medical records (allergic N=7,744, nonallergic N=15,587). Daily mean PM2.5 and temperature were obtained from a centralized monitor. Time-stratified case-crossover analyses were conducted matching on month and day of week for the time period December 2011 - June 2017. Associations of 3-day moving average (lag 0, lag 1, lag2) PM2.5 concentrations were estimated separately by asthma phenotype and adjusted for temperature and holidays. Analyses were further stratified by age (children/adult) and gender. Results: There were 49,832 acute asthma visits over the study period (21,887 among allergic patients and 27,945 among nonallergic patients). In preliminary analysis, the odds ratio (OR) for all asthma visits combined per 10 µg/m<sup>3</sup> increase in 3-day moving average PM2.5 was 1.064 (95%CI: 1.043, 1.085). The ORs for allergic and nonallergic asthma were 1.070 (95%CI: 1.038, 1.102) and 1.060 (95%CI: 1.032, 1.088) respectively. ORs for allergic and nonallergic asthma were also similar when estimated within strata of age and gender. Conclusion: Asthma visits increased 6% per 10 µg/m<sup>3</sup> increase in 3-day moving average PM2.5. Preliminary analysis showed little evidence of heterogeneity by asthma phenotype.

**P01.1510. Effects of Exposure to Air Pollution on Hospitalization for Diseases of the Musculoskeletal System and Connective Tissue Disorders in Children and Adults Living in the City of São Paulo**

Thairis Queiroz

*Thairis A. Queiroz<sup>1</sup>, Alfésio L. Braga<sup>1</sup>, Lourdes Martins<sup>1</sup>, Luiz Pereira<sup>1</sup>*

*1. Public Health Post Graduation Course, University Catholic of Santos, Santos, São Paulo, Brazil.*

Abstract: Musculoskeletal diseases (ICD 10th Revision from M00 to M25 and M40 to M99) are epidemiological relevant and economically impact the Brazilian Public Health System (SUS). The systemic diseases of connective tissue (ICD 10 th Revision from M30 to M36), although rare and affecting a low population, they are complex and multifactorial diseases, requiring complex and costly treatments for public health. Beyond well-known risk factors for these diseases, air pollutants can trigger an oxidative stress response leading to systemic inflammation. The present study aimed to evaluate the correlation between exposure to air pollutants and the possible worsening of DMSCT (Diseases of the Musculoskeletal System and Connective Tissue) in children and adults admitted to hospitals of the SUS in the State of São Paulo, from 2011 to 2016. In this ecological time series study, the effects of air pollutants on the outcomes were assessed using generalized linear Poisson regression model with an third degree polynomial distributed lag model, controlling for weather variables, seasonality and days of the week. The pollutants were within the limits of the Brazilian standards imposed during the studied period, except the O<sub>3</sub> that surpassed 296 times the state standard imposed by law. A 60,65 µg/m<sup>3</sup> increase of ozone presented an acute effect on DMSCT hospitalizations with an increase of 1.08% (IC 95%: 0,11-2,06) one day after exposure. Even though within the air quality standards, 19,26 µg/m<sup>3</sup> increases of PM<sub>10</sub> concentrations were associated with acute and delayed effects on DMSCT hospitalizations. At the same day of exposure, a 2.5% (IC 95%: 0,52-4,41) increase in hospital admissions was observed and the same effect was observed 4, 5 and 6 days after exposure. Primary and secondary pollutants were associated with DMSCT exacerbation even under air quality standards reinforcing the necessity of new parameters that minimize air pollutants adverse health effects.

## **P01.1520. Short Term Seasonal Effect of Ambient Air Pollutants and Airborne Fungal Spores on the Lung Function of School Children in Western Cape, South Africa: A Panel Study**

Toyib Olaniyan

*Toyib Olaniyan<sup>1</sup>, Mohamed Jeebhay<sup>1</sup>, Martin Röösl<sup>2</sup>, Rajen Naidoo<sup>3</sup>, Nino Küenzli<sup>2</sup>, Kees de Hoogh<sup>2</sup>, Dilys Berman<sup>1</sup>, Bhawoodien Parker<sup>4</sup>, Joy Leaner<sup>4</sup>, Mohamed A. Dalvie<sup>1</sup>*

- 2. Swiss Tropical and Public Health Institute, Basel, Switzerland.*
- 3. University of KwaZulu-Natal, Durban, South Africa.*
- 4. Department of Environmental Affairs and Developmental Planning, Cape Town, Western Cape, South Africa.*

**Abstract:** Background: Only 3 previous epidemiological studies have investigated the combined effect of short-term ambient air pollutants and fungal spores on individual level children's lung function. These studies did not investigate respiratory effects beyond 1-day lag nor investigated interaction effects. We aimed at investigating the combined effect of short-term air pollutant and fungal spore exposure on individual level lung function of school children. Methods: A panel study was conducted incorporating testing for 2 consecutive school-weeks each in summer and winter on 553 grade-4 school children from 4 informal settlements in the Western Cape Province of South Africa. Outcomes were measured using peak flow meters obtained 3-times daily concurrently at all schools. Daily PM10 levels was available from a stationary monitor near 2 of the study areas, while daily levels of fungal spores was measured using spore traps in all 4 study areas throughout the year. The effects were analysed using single- and multi-pollutant distributed lag linear and non-linear model for lags up to 5-days. Results: Daily *Alternaria* and *Cladosporium* was significantly associated with FEV1 deficit and increased PEF intraday variability, especially in winter. The strongest adverse effect was on FEV1 (-369.34 ml, 95% CI: -650 to -87.77 ml) resulting from an overall cumulative increase of 50 spores/m<sup>3</sup> in *Cladosporium* from lag day-0 through lag day-5. There was significant interaction between PM10 and *Alternaria* on reduced FEV1 ( $p < 0.001$ ) and increased intraday-variability in PEF ( $p < 0.001$ ), including PM10 - *Cladosporium* interaction on increased intraday variability in PEF ( $p < 0.01$ ), all during winter. Conclusion: The study provides evidence that daily exposure to ambient fungal spores, *Alternaria* and *Cladosporium* results in lung function deficits especially in winter. The adverse effect on lung function by the fungal spores can occur beyond the day of exposure and is modified by ambient PM10 exposure.

## **P01.1531. Effectiveness of Liquefied Petroleum Gas Stove Ownership for Reducing Household Air Pollution Exposure during Pregnancy in Guatemala**

**Abstract:** Background: Household air pollution from solid fuel use has been associated with adverse birth outcomes. Efforts to reduce exposure focused on chimney stoves have had limited success, and switching to liquefied petroleum gas (LPG) fuel is a promising alternative. Moreover, estimating a person's typical exposure has been a challenge in epidemiological studies, due to temporal variability. Objectives: We aimed to estimate the effectiveness of LPG stove ownership for reducing personal exposure to fine particulate matter (PM<sub>2.5</sub>) and describe the between- and within-person variation in exposure during pregnancy. Methods: We recruited women at <20 weeks of gestation in highland Guatemala and measured 24-hour average personal PM<sub>2.5</sub> exposure three times using an impactor with a Teflon filter and a pump. We used linear mixed effects model to estimate the variance components of log PM<sub>2.5</sub>, subject-specific typical personal exposures and the exposure reduction associated with stove ownership. Results: We obtained 559 repeated measurements from 218 pregnant women. Among them, 59 (27%) owned a LPG stove and 379 (68%) owned a chimney stove at recruitment. Typical exposure was 57 µg/m<sup>3</sup> (95%CI: 49-66) and 96 µg/m<sup>3</sup> (95%CI: 87-106) for women with and without an LPG stove, respectively. After adjusting for confounders, LPG stove ownership was associated with 41% lower personal PM<sub>2.5</sub> (95%CI: 27 to 52). Intraclass correlation coefficients was 0.51 (95%CI: 0.42-0.59) overall, and for women with and without LPG stove were 0.46 (95%CI: 0.27-0.62) and 0.46 (95%CI: 0.36-0.56), respectively. Conclusions: Effectiveness of LPG stoves for personal exposure reduction in pregnant women was moderate and might depend largely on the extent of adoption. The relatively high correlation among repeated exposure measures within individuals in this setting suggests that a small number measures per individual can provide a reliable estimation of typical exposure during pregnancy.

**P01.1532. Air Quality Management Policy and Reduced Mortality Rates in Seoul Metropolitan Area: A Quasi-Experimental Study**

Changwoo Han

*1. Department of Preventive Medicine, Seoul National University College of Medicine, Seoul, Korea (the Republic of).*

*2. Institute of Environmental Medicine, Seoul National University Medical Research Center, Seoul, Korea (the Republic of).*

*3. Environmental Health Center, Seoul National University College of Medicine, Seoul, Korea (the Republic of).*

**Abstract:** Background: The air quality management policy was introduced in Seoul and Incheon metropolitan cities in the Republic of Korea, from 2005 to 2014. Despite particulate matter concentrations decreasing after policy implementation, the consequent health benefits have not been evaluated. Objectives: We evaluated the effects of the air quality management policy on mortality rates in Seoul and Incheon. Methods: Using interrupted time series analysis with a generalized Poisson regression model, we compared daily average mortality rates before (baseline, 2004–2005) and after (2006–2007, 2008–2009, 2010–2011, 2012–2013) the policy implementation. To account for the long term mortality trends, we weighted daily mortality rate of Seoul and Incheon with daily mortality rate of Daejeon (another metropolitan city with no air quality management policy implemented). Results: Decline in the particulate matter concentration was greater in Seoul and Incheon than in Daejeon. After adjusting for potential confounders, there were 8% decrease in cardiovascular disease mortality rates and 10% decrease in cerebrovascular disease mortality rates in Seoul in 2012–2013 compared to the baseline period. In Incheon, an 8% reduction in cerebrovascular disease mortality rates in 2012–2013 was reported. There was no change in mortality rates due to external causes or other causes of deaths excluding cardiovascular and pulmonary disease after policy implementation. Conclusions: Our study suggests that the air quality management policy was effective in reducing mortality rates in Seoul and Incheon.

## **P01.1534. Source-Specific Contributions to Fine Particulate Matter Exposure Disparities in the United States**

Abstract: Efficiently addressing environmental injustice in air pollution exposure requires knowledge of the predominant sources of air pollution exposure disparities. Previous studies that have linked emissions sources to environmental injustice have used proximity to the emissions source as an exposure metric, but locations of emissions sources and the spatial patterns of the resulting concentrations are often only weakly correlated. We use the year-2014 US EPA National Emissions Inventory (NEI) and the Intervention Model for Air Pollution (InMAP) to estimate fine particulate matter (PM<sub>2.5</sub>) concentrations resulting from the more than 5,000 emissions source types included in the inventory, and we quantify associated exposure disparities by race-ethnicity. Preliminary results suggest 54% of source types, representing 62% of total PM<sub>2.5</sub> exposure, result in higher average exposures for minorities as compared to whites. Overall, minorities are exposed to average concentrations 1.7  $\mu\text{g m}^{-3}$  higher than whites. Significant source groups—those that contribute at least 1% of overall exposure—disproportionately impacting minorities include residential natural gas burning, commercial cooking, and highway vehicles (average exposure for minorities is 90%, 73%, and 39% higher, respectively, than whites). Significant source groups disproportionately impacting whites include coal power generation and agriculture (average exposure for whites is 26% and 15% higher, respectively, than minorities). These results can help policy-makers direct targeted efforts to mitigate inequitable exposure to air pollution.

## **P01.1535. Association of Indoor Air Pollutants and Cardiovascular Hemodynamics**

**Abstract:** Backgrounds: Indoor air quality has been associated with human health, however, there is limited information regarding personalized indoor air pollutants and cardiovascular hemodynamics. This study aims to investigate the concurrent real-time monitoring of indoor air quality and cardiovascular function. Methods: During July-October 2017, we recruited 40 subjects from 31 family for this study. Concurrent 24-h real-time monitoring of indoor air quality and cardiovascular hemodynamics were performed for each participant. Cardiovascular hemodynamics were measured via arterial pressure waveform by a cuff sphygmomanometer using an oscillometric BP device (DynaPulse 200M, Pulse Metric Inc., San Diego, CA). Time series analysis was applied to estimate the change of cardiovascular hemodynamics for every one unit (different scales) increase of air pollutants for 40 subjects. Results: The median (IQR) concentration of 24-hour indoor air pollutants were 28.80 (23.98)  $\mu\text{g}/\text{m}^3$  for PM<sub>2.5</sub>, 30.47(25.03)  $\mu\text{g}/\text{m}^3$  for PM<sub>10</sub>, 0.487(0.667)  $\mu\text{g}/\text{m}^3$  for carbon monoxide (CO), and 452.0 (295.0)  $\mu\text{g}/\text{m}^3$  for carbon dioxide (CO<sub>2</sub>). Time series analysis showed for every 1  $\mu\text{g}/\text{m}^3$  increase of indoor CO exposure, cardiovascular hemodynamics would increase 1.403(0.095-2.712) and 1.397(0.081-2.712) mmHg in concurrent and lag 1h systolic blood pressure respectively. In addition, the corresponding change of cardiac output would increase by 70 (13-127) ml and 73(14-132) ml for lag 1h and lag 4h respectively. For every 100  $\mu\text{g}/\text{m}^3$  increase in indoor CO<sub>2</sub> exposure, the concurrent and lag 1h cardiac output would increase by 24.1(4.9-43.3) ml and 31(12.8-49.2) ml respectively. Conclusion: Real-time indoor air quality monitoring of CO and CO<sub>2</sub> was strongly associated with personalized 24h cardiovascular hemodynamics.

**P01.1547. Ozone Chemistry over the Syrian Arab Republic: Impact of the War**

Lyazzat Kulmukanova

*Lyazzat Kulmukanova<sup>1</sup>, Mehdi Amouei Torkmahalleh<sup>1</sup>, Aigerim M. Maksot<sup>1</sup>*

*1. Chemical Engineering, Nazarbayev University, Astana, Kazakhstan.*

Abstract: Ground ozone (O<sub>3</sub>) is a major photochemical air pollutant that has negative effects on both human health and environment, exposure to which results in the development of respiratory diseases and damage to ecosystems. Ozone does not have direct natural or anthropogenic sources of emission and its formation is accounted for the cyclic photochemical reaction between its precursors, nitrogen dioxide (NO<sub>2</sub>) and volatile organic compounds (VOC). This study investigated ozone concentration and chemistry over Syrian cities Deir ez-Zor and Aleppo between 2005 and 2016. These two cities experienced a civil war in 2011 that later on involved other countries. To identify how the trends of NO<sub>2</sub> and VOC were changed due to the war, and subsequently their effect on the ozone formation, the study was divided into two periods, before and after the war. This study was conducted by analyzing Formaldehyde-to-Nitrogen Dioxide ratio (FNR), which is considered to be the main indicator of ozone sensitivity regime. It was observed that starting the war, Aleppo, located on the west of Syria experienced a change of FNR values from the range of 0-1 to 1-2 which represents a shift in ozone sensitivity regime. The city located on the east of the country, Deir ez-Zor, did not experience a considerable change in the regime, as FNR values were maintained above 2 throughout the given period. Such different responses to the presence of the war in the cities of the same country could emphasize that the war has variant effects on the ozone chemistry over the cities due to the intensity of the war interactions and background of the cities. Lastly, it was found that changes in ozone chemistry in Syria due to the war resulted in the similar changes in ozone chemistry in the bordering countries (Turkey and Lebanon), and thus areas of these countries which are close to the borders of Syrian Arab Republic experienced ozone peaks in 2012 and 2016 due to the sharp increases of ozone in Syria itself.

## **P01.1548. Modelling Indoor PM<sub>2.5</sub> and BC in Slum Homes of Mumbai, India**

Abhay Anand

*Abhay Anand<sup>1</sup>, Arpan Patra<sup>1</sup>, Harish C. Phuleria<sup>1</sup>*

*1. CESE, IIT Bombay, Mumbai, Maharashtra, India.*

Abstract: Slums which house >50% of the population in Mumbai city (~20 million), are mostly located in the peripheries of major traffic arteries thus facing high risk to air pollution. The objective of this paper is hence to identify the determinants of indoor PM<sub>2.5</sub> and black carbon (BC) in the slum homes and develop predictive indoor models for the same. Multivariate regression models are developed using log-transformed indoor measurements in 40 non-smoking homes and outdoor measurements at a background site in a slum in Mumbai, information on S.E.S. characteristics, building characteristics and activity patterns and publicly available data from central air monitors and geographic information system. Outdoor concentration in the slum is the crucial determinant of both indoor PM<sub>2.5</sub> and BC. Outdoor PM<sub>2.5</sub> is influenced by the proximity to all major roads (especially the internal major roads with congested traffic) whereas BC is influenced by the proximity to the major roads with significant truck traffic. Number of windows and presence of exhaust fan outlets on the wall increased the indoor PM<sub>2.5</sub>, suggesting increased infiltration of outdoor PM<sub>2.5</sub> at higher air exchange rates. Surprisingly, none of the indoor pollutant sources (cooking, incense burning etc.) have a significant impact on 24-hour PM<sub>2.5</sub> or BC. The study demonstrates that the indoor slum PM<sub>2.5</sub> levels could be reasonably estimated (adj R<sup>2</sup>=0.61, RMSE=0.24) using the publicly available ambient monitoring data, GIS based local traffic information, S.E.S. characteristics and home ventilation characteristics. The results show that outdoor pollution remains an important determinant for indoor air pollution in slums. Improving the traffic circulation along the congested inner roads of slum there by reducing local outdoor air pollution and ventilation control in homes during peak traffic hours may be feasible control options.

**P01.1549. Indoor Air Pollution and Reduced Lung Function in Biomass Exposed Women: A Cross Sectional Study in Pune District, India**

Rasmila Kawan

*Rasmila Kawan<sup>1</sup>*

*1. Climate change and health, Heidelberg Institute of Public Health and International Center for Integrated mountain development, Lalitpur, Nepal.*

Abstract: Indoor air pollution especially from the use of biomass fuels, remains a potentially large global health threat. The inefficient use of such fuels in poorly ventilated conditions results in high levels of indoor air pollution, most seriously affecting women and young children. The main aim of this study was to measure and compare the lung function of the women exposed in the biomass fuels and LPG fuels and relate it to the indoor emission measured using a structured questionnaire, spirometer and filter based low volume samplers respectively. This cross-sectional comparative study was conducted among the women (aged > 18 years) living in rural villages of Pune district who were not diagnosed of chronic pulmonary diseases or any other respiratory diseases and using biomass fuels or LPG for cooking for a minimum period of 5 years or more. Data collection was done from April to June 2017 in dry season. Spirometer was performed using the portable spirometer to determine the lung function over Forced expiratory volume. The primary outcome variable was forced expiratory volume in 1 second (FEV1). Secondary outcome was chronic obstruction pulmonary disease (post bronchodilator FEV1/ Forced Vital Capacity (FVC) < 70%) as defined by the Global Initiative for Obstructive Lung Disease. Potential confounders such as age, height, weight, smoking history, occupation, educational status were considered. Preliminary results showed that the lung function of the women using Biomass fuels had comparatively reduced lung function than the LPG users . The mean PM 2.5 mass concentration in the biomass user's kitchen was higher than in the LPG user's kitchen. Black carbon amount was found higher in the biomass users than LPG users . Therefore, there is an urgent need to adopt various strategies to improve indoor air quality.

## **P01.1560. Diurnal Variation of Indoor Radon Levels on Hopi Lands**

Modhi Alshammari

*Modhi A. Alshammari<sup>1</sup>*

*1. University of Arizona, Tucson, AZ, United States.*

**Abstract:** Introduction: Indoor air quality (IAQ) is essential for optimum health. To assess indoor air one needs to examine sources natural and human caused emissions in buildings. Radon is one indicator used to indicate building quality. The sources of indoor radon comes primarily from soils. In closed spaces, we find higher concentration of radon, due to lack of ventilation. It worth mention that Hopi homes lack basements. Methods: Time integrated continuous radon monitor (Sun Nuclear) was placed in nineteen homes for a 24-hour sampling period on Hopi lands during the winter season. Results: Indoor Radon concentrations varied from 0-9.5 pCi/L during the winter months. The mean concentration of radon among all houses is 1.983Ci/L. Diurnal radon concentrations are elevated between 10 p.m to 8 a.m. and decline during the day (9a.m. and 8 p.m.). Four (21%) of the homes had daily average values that exceeded action levels of Environmental Protection Agency (EPA) of 4.0 pCi/L. Discussion: There is a pattern in diurnal radon concentration associated with household ventilation patterns. During the night-time, we assume closed windows and doors leading to an accumulation of indoor radon. During the day time, ventilation reduces indoor radon levels. Homes with elevated radon concentrations suggest poor ventilation and possibly housing quality. Conclusion: The hourly results provide options in determining the type of radon reduction plans that might be recommended to families to reduce indoor radon exposure. Future analysis will include house types and location within Hopi lands.

## **P01.1570. Household Predictors of Primary Cooking Fuel Switching in Nine Low and Middle Income Countries**

Matthew Shupler

*Matthew Shupler<sup>1</sup>, Perry Hystad<sup>2</sup>, Michael Brauer<sup>1</sup>*

*1. Environmental & Occupational Health, School of Population & Public Health, University of British Columbia, Vancouver, BC, Canada.*

*2. Public Health and Human Sciences, Oregon State University, Corvallis, OR, United States.*

**Abstract:** Background: Cooking with dirty fuels (e.g. wood, animal dung, crop residue, coal and kerosene) is a major source of household air pollution (HAP), estimated to cause 2.6 million deaths in 2016. Over the last two decades, there have been many efforts to facilitate a switch from dirty fuels to clean fuels (e.g. electricity, liquefied petroleum gas and natural gas) among low-income households. Household factors that contribute to successful 'fuel switching' on a global scale are needed to inform future interventions targeting a change from dirty to clean fuels.

**Methods:** Household level data was obtained at baseline (~2003-2009, depending on location) and during the nine-year follow up period from the Prospective Urban and Rural Epidemiology (PURE) study. Survey data from 15,567 households, representative of adults aged 35-70 living in rural areas in nine countries in Asia, Africa and Latin America, with >10% dirty fuel use at baseline, was used to assess 'primary' cooking fuel switching. **Results:** Over half (8,059) of the households indicated a different primary cooking fuel between baseline and follow up. Nearly one-third (4,949) of households adopted a clean primary cooking fuel during follow up, while 13% (2,055) of households indicated primarily cooking with different types of dirty fuel between baseline and follow up.

Overall, increasing monthly household income and number of working members in the household were positively associated with clean fuel switching, while the total number of members living in the household had a negative association. There were large between and within-countries discrepancies in the rates of, and factors that affected, switching from dirty to clean fuels. **Conclusions:** In one of the most geographically and socioeconomically diverse longitudinal studies, there was an overall uptake of clean cooking energy households. Different household factors associated with fuel switching were identified between sub-national and national locations.

**P01.1580. Environmental Justice Aspects of PM2.5 Health Impacts from Electricity Generation in U.S. Power Markets**

Maninder Pal Singh Thind

*2. Engineering and Public Policy, Carnegie Mellon University, Pittsburgh, PA, United States.*

**Abstract:** INTRODUCTION Fine particulate matter (PM2.5) is considered to be the most important environmental risk factors in the global human disease burden. PM2.5 and its precursors are emitted from electricity generating units (EGUs). Environmental justice includes consideration of disproportionate impacts of air pollution by demographic group. METHODS We estimate PM2.5-related health impacts from EGUs for seven U.S. Regional Transmission Organizations (RTOs) and for each state in the contiguous U.S. Our approach uses the 2014 National Emission Inventory, the Intervention Model for Air Pollution (InMAP), and concentration-response curves from the American Cancer Society reanalysis. We investigate how health impacts vary by two demographic attributes (race; income) and for one geographic attribute (each U.S. state as a source vs receptor for PM2.5 pollution from EGU emissions). RESULTS We find "reverse EJ" for electricity generation: whites are more exposed to pollutant than non-whites nationally and within most of the US RTOs. For 36 of the 48 states in the contiguous U.S., more than half of the total premature deaths attributable to EGU PM2.5 is caused by EGU emissions in other states. Nationally, we find almost no disparity by income. The results reported here are preliminary.

**P01.1590. Environmental Justice for Criteria Air Pollutants in the United States during 1990, 2000, and 2010**

Jiawen Liu

*Jiawen Liu<sup>1</sup>, Matthew Bechle<sup>1</sup>, Lara P. Clark<sup>1</sup>, Sun-Young Kim<sup>1</sup>, Julian Marshall<sup>1</sup>*

*1. University of Washington, Seattle, WA, United States.*

**Abstract:** INTRODUCTION Environmental justice (EJ) research has documented disparities in air pollution exposure among racial, ethnic, and socioeconomic groups in the United States (US) for specific pollutants, time-points, and locations. Our study analyzes air pollution exposure disparities throughout the US, for multiple pollutants and decades. METHODS We investigate racial and ethnic disparities in exposure to outdoor annual-average concentrations of five EPA criteria pollutants (nitrogen dioxide [NO<sub>2</sub>], carbon monoxide [CO], particulate matter [PM<sub>2.5</sub>, PM<sub>2.5-10</sub>, PM<sub>10</sub>], ozone, and sulfur dioxide [SO<sub>2</sub>]) for 1990, 2000, and 2010. We employ residential concentrations estimates from our own national prediction models and demographic data from the US Census. We compare population-weighted mean outdoor concentrations by race-ethnicity. RESULTS Racial and ethnic minorities generally experienced higher average air pollution concentrations than non-Hispanic whites. In 2010, on average, exposures were higher for racial and ethnic minorities than for non-Hispanic whites, by 39.5% for NO<sub>2</sub>, 12% for PM<sub>10</sub>, 9% for PM<sub>2.5</sub>, 8% for CO, and 0.7% for ozone. From 1990 to 2010, relative exposure disparities between racial and ethnic minorities and non-Hispanic whites generally decreased (with the largest reduction for CO [from 27% to 8%], but increased slightly for NO<sub>2</sub> (from 36% to 39%). Exposures varied substantially by race-ethnicity. For example, in 2010, on average, Asians and Hispanics were exposed to higher levels of PM and NO<sub>2</sub> and lower levels of SO<sub>2</sub> and ozone, compared to non-Hispanic whites. For example, Asians experienced 9.45ppb of PM<sub>2.5</sub> and 1.38ppb of SO<sub>2</sub> while non-Hispanic whites experienced 9.08ppb of PM<sub>2.5</sub> and 1.59ppb of SO<sub>2</sub>. CONCLUSIONS Racial and ethnic minorities generally experience higher concentrations of criteria pollutants than non-Hispanic whites. Exposure disparities are generally declining over time, as pollutant concentrations decrease.

## **P01.1600. Racial Residential Segregation and Airborne Fine Particulate Matter Components in the United States**

Katherine Wolf

*Katherine R. Wolf<sup>1</sup>, Michelle Bell<sup>1</sup>*

*1. School of Forestry and Environmental Studies, Yale University, New Haven, CT, United States.*

**Abstract: Background/Aim** Both exposure to particulate matter  $\leq 2.5 \mu\text{m}$  (PM<sub>2.5</sub>) and African American racial residential segregation (RRS) in the United States (US) are associated with negative health outcomes including cardiovascular and respiratory diseases, negative birth outcomes, and death. In this study we evaluate potential associations between African American RRS and PM<sub>2.5</sub> total and component concentrations in US urban areas. **Methods** We calculated 2005-2015 average census tract concentrations of total PM<sub>2.5</sub> (n=886) and aluminum (n=276), ammonium ion (NH<sub>4</sub><sup>+</sup>) (n=213), arsenic (As) (n=276), bromine (Br) (n=274), calcium (n=276), chlorine (n=276), copper (Cu) (n=275), elemental carbon (EC) (n=201), iron (Fe) (n=276), lead (Pb) (n=276), mercury (n=162), nickel (Ni) (n=276), nitrate ion (NO<sub>3</sub><sup>-</sup>) (n=267), silicon (n=276), sodium (n=264), sodium ion (n=213), sulfate ion (SO<sub>4</sub><sup>2-</sup>) (n=277), titanium (n=276), vanadium (V) (n=276), and zinc (Zn) (n=276) using daily averages from the US Environmental Protection Agency. We used 2010 US Census data to calculate a spatial isolation (SI) index of RRS by census tract and 2008-2012 American Community Survey data to evaluate socioeconomic confounding. We used a one-way analysis of variance to evaluate differences in PM<sub>2.5</sub> total and component concentrations by SI quintile and linear models to evaluate associations between PM<sub>2.5</sub> concentrations and SI quintiles. **Preliminary Results** In preliminary analyses, concentrations of total PM<sub>2.5</sub> and As, Br, Cu, EC, Fe, Ni, NO<sub>3</sub><sup>-</sup>, Pb, SO<sub>4</sub><sup>2-</sup>, V, and Zn were higher for tracts in the highest quintile of SI than for those in the lowest. Linear models showed a 0.41- $\mu\text{g}/\text{m}^3$  increase (95% CI: 0.27, 0.54,  $p < 0.00001$ ) in total PM<sub>2.5</sub> per one-quintile increase in SI after controlling for poverty, region, educational attainment, and percent Hispanic/Latinx. **Conclusion** Results suggest that total PM<sub>2.5</sub> concentrations are higher in more segregated areas and that associations appear to vary by PM<sub>2.5</sub> composition in the US.

**P01.1610. Asthma-Related Outcomes Associated with Indoor Air Pollutants from a Survey of School Children Residing in Informal Settlement Households of the Western Cape Province of South Africa**

Toyib Olaniyan

*Toyib Olaniyan<sup>1</sup>, Mohamed A. Dalvie<sup>1</sup>, Martin Rössli<sup>2</sup>, Rajen Naidoo<sup>3</sup>, Nino Küenzli<sup>2</sup>, Kees de Hoogh<sup>2</sup>, Bhawoodien Parker<sup>4</sup>, Joy Leaner<sup>4</sup>, Mohamed Jeebhay<sup>1</sup>*

- 1. Public Health, University of Cape Town, Cape Town, South Africa.*
- 2. Swiss Tropical and Public Health Institute, Basel, Switzerland.*
- 3. University of KwaZulu-Natal, Durban, South Africa.*
- 4. Department of Environmental Affairs and Developmental Planning, Cape Town, South Africa.*

Abstract: The health impact of indoor air pollution in informal settlement households has not been extensively studied in South Africa. This study investigated the association between asthma and common indoor exposures in a survey of school children residing in the Western Cape Province. A total of 590 children, aged 9 - 11 years, were recruited from four informal settlements in the province. The International Study of Asthma and Allergies in Children (ISAAC) questionnaire, was administered to caregivers. Pulmonary function assessment included spirometry and fractional-exhaled nitric oxide (FeNO). Phadiatop test for atopy was done. The prevalence of doctor-diagnosed asthma was 3.4% (n=20) among whom only 50% were on treatment. The prevalence of asthma symptoms (wheezing in the past 12 months) was 12.9% and 17.6% had airway obstruction (FEV1 < lower limit of normal) while 10.2% had airway inflammation (FeNO > 35 ppb). In adjusted logistic regression models, dampness, visible mould growth, paraffin-use for cooking, and passive smoking were associated with a two-fold increased risk in upper and lower airway outcomes. The strongest association was for rhinitis (adjusted odds-ratio - aOR 3.01, 95%CI: 1.45 - 6.15). There is a need for improved diagnosis of childhood asthma and indoor air quality in informal settlement households.

**P01.1620. Indoor Air Quality in Housing and Health in Women of Agua Caliente, Poncitlán, Jalisco, México (2018)**

Kenia Gonzalez Pedraza

*Kenia M. Gonzalez Pedraza<sup>1</sup>, Martha G. Orozco Medina<sup>1</sup>, Felipe D. Lozano Kasten<sup>1</sup>, Miriam S. Noriega Moreira<sup>1</sup>*

*1. University of Guadalajara, Guadalajara, Mexico.*

**Abstract:** Background / aim: In rural areas, solid fuels such as wood are usually used to cook food. In Agua Caliente, Mexico 94% of households depend on this fuel to meet their energy needs for cooking, activity that suppose the influence on indoor air quality and the health of people. The aim of this study was to characterize the levels of particulate matter in the air of the kitchens and at the same time to know the thermal comfort index to which cooks are exposed in the home and the symptoms they perceive. Methods: It was measured in the indoor air of the kitchens the number of particles/ft<sup>3</sup> of the particles with diameter 0.3  $\mu\text{m}$ , 0.5  $\mu\text{m}$ , 1  $\mu\text{m}$ , 2.5  $\mu\text{m}$ , 5  $\mu\text{m}$  y 10  $\mu\text{m}$  issued by 30 stoves that use wood as fuel (14 traditional stoves and 16 ecological stoves), at the same time values of ambient temperature and relative humidity were taken and the home cooks were interviewed to know the symptoms that they manifest. Descriptive and statistical determinations were made to analyze emissions, thermal comfort index and symptoms. Results: The amount of particulate material/ft<sup>3</sup> for all particle sizes measured at the precautionary and danger levels for humans were found in more than 60% of the houses, the emissions of MP0.3, MP0.5, MP2.5 from ecological stoves and traditional stoves at these levels were found in more than 80% of homes, the thermal comfort index considered in caution, extreme caution and danger showed a tendency to occur in a greater percentage in homes with traditional stoves > 64% compared to 31% of homes with ecological stove at the precaution level. 93% of the women reported not having any symptoms associated with the use of the wood stove. Conclusions: The study showed that both ecological stoves and traditional stoves generate emissions of particles that are injurious to health, a situation that is not reflected in the symptoms perceived by women; the thermal comfort index showed improvement when using ecological wood stoves.

## **P01.1630. Ambient Particulate Matter and Incidence of Respiratory Infection in Children: A Time Series Analysis in Urban Bangladesh**

Allison Sherris

*Allison R. Sherris<sup>1</sup>, Bilkis A. Begum<sup>2</sup>, Abdullah Brooks<sup>3</sup>, Doli Goswami<sup>4</sup>, Stephen P. Luby<sup>5</sup>, Phil Hopke<sup>6</sup>*

**Abstract:** Exposure to fine particulate matter (PM<sub>2.5</sub>) has been linked to adverse respiratory outcomes in children. However, the impact of PM<sub>2.5</sub> on child health is poorly characterized in regions with high ambient air pollution, including South Asia. This study explores associations between short-term variation in source-specific ambient PM<sub>2.5</sub> and incidence of respiratory infection among children in urban Dhaka, Bangladesh. We leverage data from health surveillance of around 5,000 children and infants between 2005 and 2014, including daily counts of physician-confirmed diagnoses from clinic visits. In addition, biweekly source-apportioned ambient PM<sub>2.5</sub> measurements were obtained for the same period. Using Poisson regression adjusted for time-varying covariates, we estimate associations between ambient PM<sub>2.5</sub> and respiratory infection at time lags of zero to seven days. We find that PM<sub>2.5</sub> exposure is associated with an increase in respiratory-related clinic visits at a time lag of two days, and that this association may be driven by increased incidence of lower respiratory infection. For example, a 10 µg/m<sup>3</sup> increase in two-day lagged ambient PM<sub>2.5</sub> is associated with a 5.1% increase in pneumonia incidence (95% confidence interval = 1.9 - 8.5). The same variation in total PM<sub>2.5</sub> was associated with a smaller and nonsignificant increase in upper respiratory infection (URI). Analysis of source-apportioned fine PM indicate that secondary sulfate and the factor attributable to zinc and plastics recycling are most strongly associated with incidence of pneumonia and URI. Results suggest that PM<sub>2.5</sub> exacerbates respiratory infections in children, and that ambient air pollution contributes to the high incidence of pneumonia in urban Dhaka.

## **P01.1640. Preliminary Assessment of Indoor PM2.5 Concentrations in Households on Hopi Lands**

Steve Hadeed

*Steve Hadeed<sup>1</sup>, Modhi A. Alshammari<sup>1</sup>, Morris Paukgana<sup>2</sup>, Greg Sehongva<sup>2</sup>, Lori Joshweseoma<sup>2</sup>, Robert Canales<sup>1</sup>, Robin Harris<sup>1</sup>, Mary Kay O'Rourke<sup>1</sup>*

*1. University of Arizona, Tucson, AZ, United States.*

*2. The Hopi Tribe, Kykotsmovi, AZ, United States.*

**Abstract:** Introduction: Household reliance on biomass and solid fuels has resulted in an estimated 4.3 million pre-mature annual deaths globally. Despite the prevalent use in developing nations, recent studies suggest that low income rural populations of the United States, and other affluent countries, may experience similar exposures to HAPs due to incomplete combustion of fuels indoors. Methods: Indoor 24-hour PM2.5 concentration was measured during 2 winter heating seasons (2017 & 2018) and 1 summer non-heating season (2017) using real-time area monitors (pDR-1500) set at 1-minute logging intervals. Average 24-hour indoor PM2.5 concentration was compared across household primary heating fuel type during heating and non-heating seasons. Results: To date, 26 homes have been sampled during the heating season, of which 11 have complete follow-up data during the non-heating season. Indoor mean (SD) PM2.5 concentration in all households was 30.0 µg/m<sup>3</sup> (120.8), and was 40.3 µg/m<sup>3</sup> (145.8) during heating seasons and 9.9 µg/m<sup>3</sup> (30.1) during the non-heating season. Coal-wood burning homes had indoor PM2.5 concentration of 57.9 µg/m<sup>3</sup> (185.8) during heating (n=9) and 8.4 µg/m<sup>3</sup> (19.3) during non-heating season (n=6). During the burning season, electrically heated (5.3 µg/m<sup>3</sup> (5.8)) and electric-natural gas heated (9.9 µg/m<sup>3</sup> (9.4)) homes had the lowest 24-hour concentration compared to homes that burned a combination of wood, coal & electricity (42.1 µg/m<sup>3</sup> (156.8)), and coal, wood & natural gas (49.3 µg/m<sup>3</sup> (111.3)) for heating. Discussion: Households that primarily burn wood and coal for heat had elevated indoor PM2.5 concentrations compared to homes heated with other fuel types. Even in homes using a combination of natural gas and electricity with wood and coal, indoor levels exceeded the EPA 24-hour ambient standard of 35 µg/m<sup>3</sup>. This project will continue to monitor indoor air quality and recruit households on the Hopi Lands.

## **P01.1650. Spatiotemporal Patterns of Critically Ill Small Newborns and Industrial Air Pollutants**

Charlene Nielsen

*Charlene Nielsen<sup>2</sup>, Carl Amrhein<sup>3</sup>, Prakesh Shah<sup>4</sup>, Dave Stieb<sup>5</sup>, Alvaro Osornio Vargas<sup>1</sup>*

- 1. Pediatrics, University of Alberta, Edmonton, AB, Canada.*
- 2. Earth and Atmospheric Sciences & Pediatrics, University of Alberta, Edmonton, AB, Canada.*

- 5. Population Studies Division, Health Canada, Vancouver, BC, Canada.*

**Abstract:** Introduction: Critically ill small newborns are those who are admitted to neonatal intensive care units and have a birthweight below the 10th percentile for gestational age and sex according to Canadian normative data. These are life-threatening and costly events requiring further understanding of risk factors. We assessed spatiotemporal hot spots of critically ill small newborns and industrial air emissions, an infrequently studied source of shared exposures. Methods: Using neonatal admission data of participating NICUs in the Canadian Neonatal Network from 2006-2010, we aggregated residential postal codes from nineteen census metropolitan areas (CMA) into space-time cubes and applied emerging hot spot analyses. Using National Pollutant Release Inventory data and Environment Canada weather station data, we modelled monthly dispersion of air emissions and input the results into the analyses. We compared: (i) the resulting categorical patterns using Spearman's correlation; and (ii) binary patterns using logistic regression, with industrial land use, low socioeconomic status, and the total number of 0-4-year olds for the entire study period as covariates. Results: Fifty-two pollutants exhibited statistically significant associations with small newborn hot spots. Positive correlations of hot spots were observed with three different pollutants ( $\rho > 0.4$ ,  $p < 0.05$ ) in Winnipeg, Kingston, and Vancouver, with 22 different pollutants (beta range 0.29-1.10,  $p < 0.05$ ) in the combined nineteen CMAs, and with up to 32 emissions in eight individual CMAs. The 9 most significant pollutants were Methanol, Ethylbenzene, Toluene, Styrene, Xylene, Acenaphthylene, Isopropyl alcohol, Methyl ethyl ketone, and Nickel. Conclusion: Hot spot patterns differed among CMAs. Air pollutant emissions were geographically specific and may help explain the space-time trends of critically ill small newborns.

*3. Laboratory of Physiology, University of Cheikh Anta Diop, Dakar, Senegal.*

**Abstract:** Introduction Traffic-related air pollution has been well documented to be associated with increased risks of airway diseases. Bus drivers are exposed to hazards resulting from the inhalation of pollutants from traffic. This study was designed to describe the frequency of chronic respiratory symptoms and illnesses as well as its related factors and to assess lung functions among bus drivers. **Methods** This was a cross-sectional study conducted among the bus drivers in HLM, Medina, and Petersen districts, Dakar, Senegal. A total of 178 adult men were assessed using a questionnaire inquiring about socio-demographic, respiratory symptoms, toxicological medical evaluation, and lung function tests. Logistic regression analysis was done to determine the relationship between various socio-demographic, occupational factors, respiratory symptoms and the respiratory diseases (chronic obstructive pulmonary disease and asthma). **Results** The results of the study show that 57.9% of bus drivers had a chronic cough, 65.7% had common cold and 53.4% had recurrent headaches. A predominance of these abnormal symptoms was noted in bus drivers located in the HLM district. Lung function tests showed that 38.8% of bus drivers had asthma and 30.3% of COPD. Multivariate analysis found that frequent cold increased the risk of having asthma (OR = 6.3, 95% CI: 1.12-35.79, p = 0.03) and COPD (OR = 7.7, 95 % CI: 1.14-52.8, p = 0.03). The respiratory health status of bus drivers depends on the work area (OR = 3.2, 95% CI: 1.13-9.31, p = 0.02). **Conclusion** Chronic exposure to air pollution from traffic is associated with respiratory symptoms and diseases and reduced lung function indices among bus drivers. **Keywords:** Air pollution, Bus drivers, Senegal, Asthma, COPD.

## **P01.1680. Characterisation of Fine Particulates in Different Commute Modes in Mumbai**

Arpan Patra

*Arpan Patra<sup>1</sup>, Abhay Anand<sup>1</sup>, Harish C. Phuleria<sup>1</sup>*

*1. Center for Environmental Science and Engineering, Indian Institute of Technology Bombay, Mumbai, MAHARASTRA, India.*

**Abstract:** The growth of urban population leads to an increase in travel demand which in turn aggravates urban air pollution as well. A number of studies have assessed in-cabin particulate levels in different commute modes but its chemical composition is not well studied. Moreover, there is a dearth of such studies in cities in low and middle-income countries. The aim of this study is to quantify black carbon (BC) and fine particulate matter (PM<sub>2.5</sub>) and its chemical constituents in different commute modes in Mumbai. Additionally, we aim to estimate the population attributable exposure to traffic-related air pollutants due to commute in Mumbai. PM<sub>2.5</sub> (real-time and gravimetric) and BC are measured in buses (AC and non-AC), Non-AC City trains, taxis, auto-rickshaws and motorbikes. Measurements are done on weekdays during morning rush (8:00-11:00) afternoon non-rush (13:00-16:00) and evening rush (18:00-21:00) hours from Nov 2017 to Apr 2018. A minimum of 6 commute trips are made in each transportation mode travelling a fixed route (~9 Km) with a concurrent measurement at a fixed urban background location. PM<sub>2.5</sub> and BC are 1.4 and 1.6 times higher during traffic rush hours than the non-rush hours, respectively. The mean  $\pm$ SD concentration of PM<sub>2.5</sub> inside non-AC buses, AC buses, city trains, taxis, auto-rickshaws and motorbikes are  $126 \pm 16 \mu\text{g}/\text{m}^3$ ,  $55 \pm 23 \mu\text{g}/\text{m}^3$ ,  $242 \pm 8 \mu\text{g}/\text{m}^3$ ,  $122 \pm 20 \mu\text{g}/\text{m}^3$ ,  $138 \pm 14 \mu\text{g}/\text{m}^3$  and  $142 \pm 17 \mu\text{g}/\text{m}^3$ , respectively. Corresponding BC levels are  $43 \pm 6 \mu\text{g}/\text{m}^3$ ,  $11 \pm 3 \mu\text{g}/\text{m}^3$ ,  $28 \pm 8 \mu\text{g}/\text{m}^3$ ,  $38 \pm 5 \mu\text{g}/\text{m}^3$ ,  $49 \pm 11 \mu\text{g}/\text{m}^3$  and  $55 \pm 7 \mu\text{g}/\text{m}^3$ , respectively. City trains have ~2 times higher levels than other modes. Non-AC buses have similar concentrations as taxis, autos and motorbikes but ~3-4 times higher in-cabin pollutants levels than the AC buses, indicating efficient filtration of the on-road exhaust particles. Effect of road traffic characteristics on vehicular in-cabin pollutants' levels and chemical characterization of PM<sub>2.5</sub> are currently underway.

**P01.1690. Particulate Matter and Black Carbon Personal Exposure Reductions from an LPG Stove Intervention in Rural Households in Puno, Peru: Preliminary Results**

Magdalena Fandiño Del Rio

*Magdalena Fandiño Del Rio<sup>1</sup>, Josiah Kephart<sup>1</sup>, William Checkley<sup>2</sup>, Kirsten Koehler<sup>1</sup>*

*1. Department of Environmental Health and Engineering, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States.*

*2. Division of Pulmonary and Critical Care, School of Medicine, Johns Hopkins University, Baltimore, MD, United States.*

Abstract: Household air pollution (HAP) from biomass fuels is a leading risk factor for preventable diseases and among the largest environmental contributor to the global disease burden. Previous interventions show limited results with concentrations that remain significantly higher than recommended guidelines and therefore show limited results in improving health. As a result, recent efforts are focusing on stoves that use cleaner fuels such as liquefied petroleum gas (LPG). A randomized controlled field trial of an LPG stove intervention is enrolling 180 female participants and will follow them for one year. Free LPG stoves and fuel are being delivered to 90 participants. We are collecting 48-hour measurements of personal exposure to fine particulate matter (PM<sub>2.5</sub>) and black carbon (BC). Preliminary data shows baseline daily average personal PM<sub>2.5</sub> exposures of 120 µg/m<sup>3</sup> among biomass fuel users (n=70). We observed preliminary reductions of about 80% and 78% on average personal exposure to PM<sub>2.5</sub> after the first and third month of LPG stove use respectively, compared to baseline concentrations (n=20). Personal BC exposures of about 40 µg/m<sup>3</sup> were reduced by 90% after one and three months of LPG stove use (n=25). Preliminary results show not only sharp exposure reductions expected from good compliance after one month, but also sustained reductions from the LPG stove use after three months of the intervention. Results from this analysis will provide valuable information to help understand PM and BC exposure from biomass fuel use. In addition, findings from this study will help us better understand the HAP changes that follow the adoption of LPG stoves. Results of this trial will inform the feasibility of an LPG stove replacement program to reduce HAP and improve health in resource-limited settings such as Peru.

## **P01.1700. Modeling the Impact of Indoor Air Purifier on Air Pollution Exposure Reduction and Associated Health Benefits in Urban Delhi Households**

Jiawen Liao

*Jiawen Liao<sup>1</sup>, Wenlu Ye<sup>1</sup>, Tom Clasen<sup>1</sup>*

*1. Department of Environmental Health, Emory University, Atlanta, GA, United States.*

**Abstract:** Background: Households in urban Delhi experience elevated level of ambient and indoor air pollution. Indoor air filtration is recommended as a measure to improve indoor air quality, yet few studies have examined the effectiveness of air filtration devices in urban settings in low- and middle-income countries. This study aims to quantify the impact of household air purifier on indoor air quality and its health implications. Methods: We used CONTAM 3.2 (National Institute of Standard Technology) to simulate the indoor personal PM<sub>2.5</sub> exposure of the primary cook over 12 months in a typical one-bedroom apartment in urban Delhi. We conducted a factorial design to model PM<sub>2.5</sub> exposure as a function of air filter type (low, medium efficiency and HEPA filter), use schedule (8 hour, 15 hour and all day) and presence of another smoker. Based on the simulated exposure reduction, we employed the Household Air Pollution Intervention Tool (HAPIT) to estimate the corresponding health benefits on major conditions. All model inputs were extracted from governmental/scientific literature. Results: The modeled annual personal PM<sub>2.5</sub> exposure without air purifier was 111  $\mu\text{g}/\text{m}^3$  and 145  $\mu\text{g}/\text{m}^3$  for households without and with a smoker, respectively. The highest exposure reduction occurred in scenarios with all-day use of air purifier equipped with HEPA filter. The annual personal PM<sub>2.5</sub> level was reduced to 33 and 34  $\mu\text{g}/\text{m}^3$  for households without and with a smoker. These PM<sub>2.5</sub> reductions represent 48 and 43 deaths averted per 100,000 population per year. Simulated annual personal exposures to PM<sub>2.5</sub> from 8-hour and 15-hour use of air purifier all exceeded the WHO interim guideline at 35  $\mu\text{g}/\text{m}^3$ , mainly due to the infiltration of ambient air pollution. Conclusions: Our simulation shows that consistent use of household air purifier can reduce indoor air pollution in a city like Delhi. The reduced personal indoor air pollution exposure from air filtration can result in significant health benefits.

## **P01.1710. Liquefied Petroleum Gas as a Clean Cooking Fuel: Adoption and Use in Rural India**

Carlos Gould

*Carlos F. Gould<sup>1</sup>, Johannes Urpelainen<sup>2</sup>*

*1. Environmental Health Sciences, Columbia University Mailman School of Public Health, New York City, NY, United States.*

*2. School of Advanced International Studies, Johns Hopkins University, Washington DC, DC, United States.*

**Abstract:** **BACKGROUND:** One million premature deaths in India can be attributed to household air pollution (HAP) from the combustion of solid fuels for cooking. In response, the Indian government has developed policies to increase adoption of liquefied petroleum gas (LPG) in rural Indian households, aiming for adoption in 80% of households by 2019. Indeed, LPG is the most popular clean cooking fuel in rural India, but how rural households use it remains poorly understood. Importantly, exclusive use of clean cooking fuels is needed to reduce health risks from HAP exposure. **METHODS:** We employ the 2014-2015 Access to Clean Cooking Energy and Electricity household survey (N=8,568) from six energy-poor states to describe LPG in rural India, outlining: (i) reasons for LPG non-adoption; (ii) fuel stacking and specific dishes cooked with LPG; and (iii) cooking satisfaction and fuel perceptions. **RESULTS:** Both LPG stove (N=6376) and fuel (N=5907) costs were common reasons for LPG non-adoption (N=6712). Fewer than 60% of LPG users considered it their primary fuel, and exclusive use was rare (N=386). The remaining 40% mostly used LPG to prepare tea and snacks. While satisfaction with LPG was high (78%), three-quarters of households using LPG as a supplemental fuel cite fuel costs as a reason for dissatisfaction. For these households, the cost of one 15 kg LPG cylinder accounted for 10% of total monthly expenditures. **CONCLUSIONS:** LPG was popular among users, but fuel costs limited exclusive use. As observed elsewhere, study households likely ration LPG use by avoiding fuel-intensive dishes, limiting cooking primarily to tea and snacks. While LPG use offers great promise in rural India and numerous policy initiatives promote adoption, limited fuel affordability promotes continued woodfuel use, potentially limiting the health benefits obtained through LPG programs that focus primarily on promoting adoption.

**P01.1721. An Evaluation of Speciated Plasma Arsenicals as Potential Biomarkers of Arsenic Exposure and Arsenic-Associated Diabetes in Individuals Living in Zimapan and Lagunera, Mexico**

**Abstract:** Background: Exposure to inorganic arsenic (iAs) remains a public health issue. Typically, three major forms of arsenic are measured in urine as biomarkers of iAs exposure, namely, iAs, and its metabolites, monomethylated arsenic (MMAs) and dimethylated arsenic (DMAs). This study is among the first to examine speciated plasma arsenicals as biomarkers of iAs exposure and iAs-associated disease, namely, diabetes mellitus (DM). Methods: Drinking water and plasma samples were collected from participants in the Zimapan and Lagunera cohort (N = 258). The relationships between drinking water iAs and plasma arsenicals were examined using both spearman correlations and multivariable linear regression models. Multivariable linear and logistic regression models were used to estimate the mean difference (95% CI) for the relationship between plasma arsenicals and diabetes indicators and the odds ratio (95% CI) for the relationship between plasma arsenicals and DM. Results: Plasma arsenicals were associated with drinking water iAs, with spearman correlation coefficients of 0.45 for P-MMAs, 0.48 for P-DMAs and 0.41 for total arsenic (P-tAs;  $p < 0.0001$ ). After adjusting for potential confounders, there were significant associations between log-transformed plasma arsenic and log-transformed diabetes indicators. Specifically, an interquartile range (IQR) increase in P-iAs was associated with fasting plasma insulin (0.089 (95% CI: 0.025, 0.153)), insulin resistance (HOMA-IR; 0.084 (95% CI: 0.017, 0.152)), and beta cell function (HOMA-B; 0.133 (95% CI: 0.007, 0.259)). Plasma arsenicals were not associated with the odds of DM. Conclusions: Speciated plasma arsenicals were associated with drinking water iAs, suggesting that they may serve as biomarkers of iAs exposure. Increases in fasting plasma insulin, HOMA-IR, and HOMA-B in the absence of changes in glycemia, indicate that plasma arsenic may be related to subclinical changes in pancreatic beta cell function that underlie DM development.

## **P01.1730. Exposure to Arsenic in Yellowknife, Northwest Territories, Canada**

Janet Cheung

*Janet Cheung<sup>1</sup>, Rajendra P. Parajuli<sup>1</sup>, Renata Rosol<sup>1</sup>, Claudia Tanamal<sup>1</sup>, Laurie Chan<sup>1</sup>*

*1. Biology, University of Ottawa, Ottawa, ON, Canada.*

Abstract: Giant Mine, located in Yellowknife, Northwest Territories, is regarded as one of the most contaminated sites in Canada. Gold extraction from arsenopyrite ores left behind a legacy of 237,000 tonnes of arsenic trioxide stored in the inactive mine's underground chambers. Contamination of such scale is of public health concern due to the potential hazard of arsenic and other chemical exposures to the Yellowknife population as well as the local Indigenous communities: Yellowknives Dene First Nation and members of the North Slave Métis Alliance. The objective of this study is to investigate arsenic exposure in the human population of Yellowknife using a biomonitoring approach with a longitudinal cohort design. We postulate that exposure levels in the Yellowknife population are similar to that of the Canadian population, resulting in no observable effects. A community-participatory approach is used for the development of the study design. Consultations with local stakeholders started in 2016 leading to the establishment of an Advisory Committee that oversees all aspects of the study. Baseline data are to be collected from 10% of Yellowknife households through random selection, representative of the population, and volunteer participants from the Indigenous communities from 2017-2018. Urine, toenail and saliva samples are being collected from about 2000 participants ranging from 3 to 79 years old. Total and arsenic species concentrations in urine and toenails are measured using LC-ICP-MS, and compared to the data reported by the Canadian Health Measures Survey. Saliva samples are collected for the analysis of 89 single nucleotide polymorphisms of genes related to arsenic metabolism. Two protein biomarkers CC16 and KIM-1 in urine samples will be measured as biomarkers for kidney and lung functions. Our research is the first comprehensive biomonitoring and health survey conducted in the area of this major contaminated site in Canada.

## **P01.1740. Incorporating Unique Exposure Pathways of the Diné People into a Community-Based Probabilistic Risk Assessment to Assess the Impacts of the Gold King Mine Spill**

Yoshira Van Horne

*Yoshira O. Van Horne<sup>1</sup>, Karletta Chief<sup>2</sup>, Mae-Gilene Begay<sup>4</sup>, Robert Canales<sup>1</sup>, Nathan Lothrop<sup>1</sup>, Nicolette Teufel-Shone<sup>3</sup>, Paloma Beamer<sup>1</sup>*

*2. Soil, Water, and Environmental Science, University of Arizona, Tucson, AZ, United States.*

*3. Northern Arizona University, Flagstaff, AZ, United States.*

*4. Navajo Nation Department of Health, WindowRock, AZ, United States.*

Abstract: On August 5th 2015, the Gold King Mine Spill released 3 million gallons of acid mine drainage-containing arsenic (As) and lead (Pb) into a tributary of the San Juan River, which flows through the Navajo Nation. The Diné (Navajo) rely on this River and use it for a variety of purposes lending to unique exposure pathways. We administered questionnaires in three Navajo communities in collaboration with the Navajo Nation Community Health Representatives to obtain frequency and duration data on 42 activities. These activities were utilized to conduct a community-based probabilistic risk assessment from exposure to As and Pb: 1) before the Spill, 2) during peak of the Spill, and 3) one year after the Spill. To estimate exposure to As and Pb before the Spill, we utilized historical surface water (n=32) and sediment data (n=20) obtained from the USGS. Estimation of exposure to As during peak Spill incorporated As and Pb surface water (n= 92) and sediment (n=75) concentrations obtained from U.S. EPA publically available data. To estimate exposure to As and Pb one year after the Spill, we collected surface water (n=101) and sediment samples (n=127) in these three Navajo communities within one year after the Spill. Surface water concentrations of As and Pb were significantly different between periods (p-value <0.0001), with concentrations highest during the peak of the Spill, followed by pre-Spill and post-Spill levels. Sediment concentrations were significantly different (p-value <0.0001), but with concentrations highest before the Spill, followed by peak-Spill, and post-Spill. The risk assessment for arsenic and lead through these unique water/sediment pathways indicate both potential chronic and carcinogenic risks to the local Diné community. This research provides the first documentation of unique exposure pathways of the Diné people and raise the need to understand and document unique exposure pathways of indigenous communities with subsistence and land-based livelihoods.

**P01.1750. Does Exposure to Organophosphate Pesticides Modify the Association of Low Neighborhood Socioeconomic Position with Greater Cognitive Decline?**

Kristina Dang

*Kristina Dang<sup>1</sup>, Beate Ritz<sup>2</sup>, Maria Glymour<sup>1</sup>, Allison Aiello<sup>3</sup>, Kimberly C. Paul<sup>2</sup>, Mary Haan<sup>1</sup>*

*1. Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA, United States.*

*2. University of California Los Angeles, Los Angeles, CA, United States.*

*3. University of North Carolina, Chapel Hill, NC, United States.*

Abstract: Adverse cognitive effects of social exposures such as neighborhood socioeconomic position (NSEP) may be exacerbated by environmental neurotoxins, including organophosphate pesticides (OP). Mexican-Americans are differentially exposed to both low NSEP and high OP. We examined synergistic associations of NSEP and OP on cognitive decline in older Mexican-Americans. The Sacramento Area Latino Study on Aging (SALSA, N=1,789 with cognitive assessments and N=430 with OP assessments), a cohort of Mexican Americans aged 60-100 who completed a modified Mini-Mental State Exam (3MS) annually from 1997 to 2008. 3MS errors were log-transformed. Total OP pesticide exposure from California Pesticide Use Reports was dichotomized at the median. Baseline NSEP was a composite of six census tract measures from the 2000 Census (Z-scored). We used multilevel linear mixed models with random intercepts for census tract and participant to estimate effects of NSEP and OP pesticide exposure on 3MS decline. We tested for interactions of NSEP and OP pesticide exposure. Models were adjusted for baseline age, gender, diabetes, baseline BMI, rural/urban residence, occupation, years of schooling, and practice effect. In the full sample, higher NSEP predicted better 3MS (B=-0.07 95% CI:-0.10 to -0.03), but not 3MS decline (B=0.004 95% CI:-0.002 to 0.01). OP pesticide exposure was not associated with 3MS scores (B=-0.18, CI:-0.37 to 0.015), and did not predict decline (B=0.03 95% CI:-0.006 to 0.06). For those exposed to OP pesticides, each unit increase in NSEP was associated with 0.09 (CI: -0.15 to 0.32) better 3MS, compared to 0.08 (CI: -0.14 to 0.01) worse 3MS for people not exposed to OP pesticides, but these differences may have been due to chance (p=0.273 for the interaction). Higher NSEP predicted better cognitive scores, and higher OP pesticide exposure was associated with cognitive decline. We found little evidence for a qualitative interaction between NSEP and OP.

## **P01.1760. Low-Moderate Arsenic Exposure and Respiratory Health in American Indian Communities**

- 7. Analytical Chemistry, Institute of Chemistry, Graz, Austria.*

**Abstract:** Background: Exposure to inorganic arsenic through drinking water is an established cause of lung cancer. However, evidence on the impact of arsenic exposure on non-malignant lung disease is less conclusive. The available evidence, mostly from populations exposed to water arsenic levels >100 µg/L, suggests that arsenic exposure is associated with lower lung function. Prospective studies and studies examining low-moderate levels (<50 µg/L), the level relevant for most populations worldwide, are limited. Methods: The Strong Heart Study is a prospective study of American Indian adults. The present analysis (n=2,166) used urinary arsenic measurements at baseline (1989-1991) and lung function measured by standardized spirometry at the second examination (1993-1995). We evaluated associations between arsenic exposure and airflow obstruction (FEV1/FVC ratio <0.70) and restrictive pattern (FVC <80% predicted with FEV1/FVC ratio >0.70); respiratory symptoms; and self-reported diagnosis of nonmalignant respiratory disease. Results: Airflow obstruction was present in 21.5% (458/2,132), and a restrictive pattern was present in 18.3% among those without obstruction (307/1,674). The odds ratio (95% confidence interval) for obstructive and restrictive patterns comparing the IQR of arsenic (µg/g creatinine) was 1.13 (0.96, 1.32) and 1.27 (1.01, 1.60), respectively, after full adjustment, including smoking, kidney function, and history of tuberculosis. Self-reported diagnosis of emphysema, frequent cough, phlegm with cough, and stopping for breath were also positively associated with arsenic. Conclusions: In this American Indian population, low-moderate inorganic arsenic exposure was positively associated with a lung restrictive pattern, higher self-reported emphysema, and respiratory symptoms, independent of smoking status. These findings suggest that low-moderate arsenic exposure can contribute to nonmalignant lung disease and may be associated with restrictive lung disease.

## **P01.1770. A Validated Environmental Health Literacy Scale to Improve Community Protection**

Cecilia Alcala

*Cecilia S. Alcala<sup>1</sup>, Arti Shankar<sup>2</sup>, Mya Sherman<sup>1</sup>, Jeffrey Wickliffe<sup>1</sup>, Hannah Covert<sup>1</sup>, Mark Wilson<sup>1</sup>, Maureen Y. Lichtveld<sup>1</sup>*

*1. Global Environmental Health Sciences, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA, United States.*

*2. Global Biostatistics and Data Science, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA, United States.*

**Abstract:** Background: Environmental health literacy (EHL) is essential for the general public's understanding of what and how environmental factors impact health. While several EHL tools exist, it is not clear if these have been validated. Methods: A three-pronged strategy was used to create the general EHL scale: 1) Item Generation- Using a Delphi approach, a group of environmental health (EH) scientists generated key items to be included in the scale, categorized into three domains: knowledge, attitude, and behavior. In the context of the study, knowledge is defined as EH facts and information gained through experience or education; attitude refers to a settled way of thinking or feeling about EH; and behavior is defined as the way in which an individual acts in response to EH concerns; 2) Item Review- The strongest items in each domain were selected by additional EH experts for inclusion in the scale; and 3) Scale Validation- The scale was then validated by two separate groups: 174 public health students and 98 community participants. The scale's factor structure was based on exploratory factor analysis (EFA) for the first group, while the model fit was assessed through confirmatory factor analysis (CFA) for the second group. Results: EFA analysis resulted in a three-factor solution. Three groups of model fit indices were used in the CFA analysis to assess model fitness; all indices indicated a good fit. Discussion: The resultant 9-item scale is psychometrically sound. This validated EHL scale will strengthen a broad range of EH research, bolster community engagement and citizen science, advance the efficacy of EH interventions, and build EH practice capacity. Three additional environmental media-specific subscales are currently being analyzed (air, water, food) and will further enhance the relevance of this general EHL scale.

**P01.1790. Knowledge and Awareness of Health Effects Related to the Use of Mercury in Small-Scale Artisanal Gold Mining in Suriname**

Paul Scheepers

*Ilse Ottenbros<sup>1</sup>, Romilda Boerleider<sup>1</sup>, Bianca Jubitana<sup>2</sup>, Nel Roeleveld<sup>1</sup>, Paul T. Scheepers<sup>1</sup>*

*1. Health Evidence, Radboud University Medical Center, Nijmegen, Netherlands.*

*2. Medische Zending Primary Health Care Suriname, Paramaribo, Suriname.*

**Abstract:** The use of mercury in artisanal and small-scale gold mining has negative effects on human health and the environment. To reduce the use of mercury and subsequent health impact to gold miners and local inhabitants, knowledge and awareness in the community should be raised. This study evaluates the intervention effect of a health education programme on the levels of knowledge and awareness among local inhabitants and small-scale gold miners in active gold mining areas in the interior of Suriname, South-America. For this a total of 961 unique local inhabitants and 140 gold miners were interviewed. The interviews covered five topics: general knowledge of mercury, potential routes of exposure, health risks to children and adults, mercury related health effects and reproductive health risks. Additionally, participants were asked about potential exposure reduction techniques, and their willingness to participate in a future human biomonitoring programme. The health education programme influenced mainly knowledge on exposure routes of mercury (increase from 64% to 78% of the respondents who could name the relevant exposure routes) and knowledge on health effects attributed to mercury (increase from 48% to 70% of the respondents who were able to list the correct health effects). 70% of the respondents affirmed the higher sensitivity of children, and knowledge on reproductive health effects increased from 39% to 63%. Self-estimated levels of knowledge also increased, indicating higher levels of confidence. Gold miners reported to be willing to improve their work procedures (e.g. burning amalgam with a retort). However, suitable tools were not always available. Almost all respondents were willing to give consent for participation in a future human biomonitoring programme, for both themselves and their children. The implementation of a health education programme within a local healthcare structure proved effective and levels of knowledge and awareness improved.

## **P01.1800. Effect of Environmental Factors on Tuberculosis Patients Treatment Response at Lower Rift Valley, Southern Ethiopia**

Adane Shana

*Adane W. Shana*<sup>1</sup>

*1. Aklilu Lemma Institute of Pathobiology, Addis Ababa University, Addis Ababa, Ethiopia.*

**Abstract:** Background: Emergence of Mycobacterium tuberculosis (Mtb) drug resistance strains mainly associated to the environmental factors exacerbating the global health crisis. Monitoring of immune response to anti-mycobacterial therapy can contribute to assess the effectiveness of a drug therapy. Objective: To explore the environmental factors affecting tuberculosis (TB) patients' immune response to the first line anti-tb drugs. Methods: Longitudinal cohort study was used to evaluate treatment response of TB patients. Eligibility criteria for recruitment were positivity for Acid Fast Bacilli Stain (AFB), culture "and" OR "or" GeneXpert MTB/RIF Assay, Body Mass Index (BMI) and Interferon Gamma Release Assay (IGRA) were mainly used to evaluate treatment response. Results: The mean±sd of the BMI increased from 19±0.5 at baseline to 20.9±0.5 at the end of the treatment. The IFN-γ response had decreasing trend from baseline mean±sd = 2.09±1.09 to the end of the treatment mean±sd = 0.23±0.20. At individual patient level, there was significant variability in baseline IFN-γ level and the variability was narrowed over time. No significant gender difference (49.8% among males versus 51.2% among females; Chi-square ( $\chi^2$ ) = 0.10; P = 0.41) and the age range of 24-65 years;  $\chi^2$  = 6.91; P = 0.075. Living at highland and for the agrarians (adjusted odds ratio/AOR = 2.62, 95% CI: 1.30, 5.28; P = 0.007), and living in the same house (AOR = 2.89, 95% CI: 1.09, 7.66; P = 0.033) were significantly associated with the increasing trend of IFN-γ response. The environmental factors (lowland residency and level of humidity) and social factors had no association to the IFN-γ response during the treatment (P>0.05). Conclusions: Information related to environmental and host related risk factors are very important to control the emergence of drug resistance strain by effective monitoring of treatment response.

**P01.1810. Cobalt and Thyroid Function. Case-Control Study of Patients with Goiters in Katanga, DR Congo**

Abstract: High environmental exposure to cobalt has been documented in the general population of southern Katanga, as a result of intense mining activities. Cobalt has been shown to affect thyroid function in experimental animals and occupationally exposed persons. We aimed to determine the exposure to trace metals by biomonitoring of patients with goiters. During a government campaign offering free surgery, we included 32 adults with an untreated goiter documented by clinical and ultrasound examination, and thyroid function assessment by serum TSH, free triiodothyronine (FT3) and thyroxine (FT4). Controls (n=27) were adults undergoing surgery for various other conditions in the same hospital. Trace metals were measured in blood and spot urine samples by Inductively Coupled Plasma - Mass Spectrometry. Overall, no differences were found between trace metal concentrations of cases and controls, both groups exhibiting higher values of trace metals than reference values from industrially developed countries. Nevertheless, in 7 patients with hypothyroidism, FT4 and FT3 were negatively associated with blood cobalt (Spearman rho=-0.82) and blood cadmium (rho=-0.82), respectively. In 18 euthyroid patients, TSH was associated with blood cadmium (rho=0.54). In 7 hyperthyroid patients, TSH was associated with blood mercury (rho=-0.84). Serum FT4 was associated with urinary cobalt (rho=-0.49) and nickel (rho=-0.60) in euthyroid patients, and with urinary molybdenum (rho=0.79) and thallium (rho=-0.78) in hyperthyroid patients. This limited study found no differences in trace metal concentrations in blood or urine between untreated goiter patients and controls. However, when the heterogeneous group of untreated goiter patients was divided according to thyroid function, some associations with cobalt or other trace metals were observed. In particular, blood cobalt was negatively associated with FT4 among hypothyroid patients, thus suggesting a thyrotoxic effect of cobalt.

## **P01.1820. Temporal Distribution of Dengue Fever in Brazil from 1998 to 2017**

Denise Andrioli

*Denise C. Andrioli<sup>1</sup>, Maria A. Busato<sup>1</sup>*

*1. Programa de Pós-Graduação em Ciências da Saúde, Universidade Comunitária da Região de Chapecó, Chapecó, Santa Catarina, Brazil.*

**Abstract:** Dengue fever is considered the most widely disseminated vector-borne disease worldwide, and one of the most important public health problems. It has significant economic and social impact, especially in tropical and subtropical countries. Dengue fever is a febrile infectious disease caused by an arbovirus and transmitted in Brazil by the *Aedes aegypti* mosquito. In this country, dengue transmission has been continuous since 1986, and its first documented epidemic was recorded in 1982. **Objective:** To describe the cases of dengue fever in Brazil, reported from 1998 to 2017. **Method:** This study used the database of the Department of Informatics of the Brazilian Unified Health System and Ministry of Health Epidemiological Reports. **Results/Discussion:** Approximately 12 million cases of dengue were reported during the assessed 20-year period. Of these, nine million cases occurred in the last decade (2008 to 2017). It was observed that the number of cases increased year by year and that epidemics occur cyclically. The World Health Organization defines the level of epidemic transmission when the incidence rate is greater than 300 cases of dengue fever/100.000 inhabitants. The 1998 epidemic had an incidence of 313.8 cases/100.000 inhabitants, whereas in the year 2002 there were 398.8 cases/100.000 inhabitants. The years 2010, 2013, 2015 and 2016 were the most critical ones, with more than one million cases of dengue recorded each year. The largest epidemic occurred in 2015, with an incidence of 825.9 cases/100.000 inhabitants. In 2017, the incidence of dengue decreased considerably (121.2/100.000 inhabitants). Dengue has a seasonal pattern in Brazil, with a higher incidence in the first five months of the year, a warmer and more humid period. National policies for vector control, dengue fever prevention and clinical management of patients have progressed in the country. However, preventive actions that can minimize the impacts of dengue should be improved and constant.

## **P01.1830. Favorable Birth Outcomes in the Population of Tacna, Peru, despite Chronic Arsenic Exposure in Drinking Water**

Diego Fano

*Cinthya Vásquez<sup>1</sup>, Diego Fano<sup>1</sup>, Vilma Tapia<sup>1</sup>, Sandra Yucra<sup>1</sup>, Gustavo F. Gonzales<sup>1</sup>*

*1. Facultad de Ciencias y Filosofía, Universidad Peruana Cayetano Heredia, Lima, Peru.*

Abstract: Tacna is a southern region of Peru, bordering with Chile and Bolivia. It presents valleys, sandy soils and inactive volcanoes. As it happens with Northern Chile and Argentina, Tacna possess high levels of arsenic in water, reaching values of 0.6812 mg/L, many times above the limit established by WHO (0.01 mg/L). The arsenic present have a geogenic origin derived from volcanic rocks. It is well known that continuous exposure leads increases risks of morbidity and mortality as different kinds of cancers, cardiovascular diseases and diabetes. Arsenic is able to cross the placenta, causing low birth weight, small for gestational age (SGA) and preterm birth. A recent work from our laboratory found extreme arsenic chronic exposure measured in drinking water in several districts of Tacna, without affecting negatively birth weight, or SGA and preterm birth prevalence as expected. In fact, these reproductive outcomes were not different according to exposure levels defined in quartiles [Q1 (0.0001-0.01 mg/L), Q2 (0.0220-0.0537 mg/L), Q3 (0.0545-0.2261 mg/L) and Q4 (0.2520-0.6812 mg/L)]. Nonetheless, arsenic speciation data was not available. These favorable birth outcomes could be evidence of 1) presence of non-toxic arsenic (organic Dimethylarsenic rather than inorganic) or 2) a positive selection for genetic polymorphisms in the gene *as3mt*; in charge of arsenic methylation, as those found in northern Chile and Argentina (San Antonio de los Cobres), conferring the fetuses a natural protection against arsenic toxicity. Given the reasons above, and the public interest, it is necessary conduct a research aimed to identify why high arsenic exposure is not associated with adverse reproductive outcome. These include measurements of urine, hair to detect different arsenic species and blood for polymorphisms e.g. *as3mt*. Group of study will be pregnant women in Tacna, in which different designs will be performed starting with a preliminary pilot study and finally a cohort study.

## **P01.1840. Using Birth Cohort Data to Estimate Prenatal Exposures for All Births around the New Bedford Harbor Superfund Site in Massachusetts**

Scott Bartell

*Roxana Khalili<sup>1</sup>, Scott M. Bartell<sup>2</sup>, Jonathan Levy<sup>3</sup>, M. Patricia Fabian<sup>3</sup>, Susan A. Korrick<sup>4</sup>, Veronica M. Vieira<sup>2</sup>*

- 4. Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States.*

**Abstract:** Introduction: Children born near New Bedford, Massachusetts, USA have been prenatally exposed to environmental chemicals, in part due to an older housing stock, high fish consumption rates, and proximity to the New Bedford Harbor (NBH) Superfund site. Chemical exposure measures are not available for the general population, limiting epidemiologic investigations and potential interventions. Our objective was to leverage available sociodemographic and biomonitoring data from the New Bedford Cohort (NBC) to retrospectively estimate prenatal exposures for all 10,273 births between 1993-1998 in the 4 towns neighboring the NBH Superfund site. Methods: The NBC, a population-based cohort of 788 mother-infant pairs born between 1993-1998 near the NBH, collected questionnaire data and prenatal exposure biomarkers including cord serum polychlorinated biphenyls (PCB), *p,p'*-dichlorodiphenyl dichloroethylene (DDE), hexachlorobenzene (HCB), cord blood lead (Pb), and maternal hair mercury (Hg). We used bootstrapped samples of the NBC data to build prenatal exposure models, with multivariable smooths of birth location, birth year, maternal age at birth, and other NBC maternal sociodemographic characteristics as predictors. Results: Maternal country of birth was the strongest exposure predictor across all exposures with women from the Azores and Cape Verde having the highest levels. Maternal age, education, and marital status also were important predictors. The PCB, DDE, HCB, Pb, and Hg exposure models explained 55%, 53%, 41%, 43% and 38% of the variance, respectively. Conclusions: Our analyses suggest that multiple prenatal exposures can be estimated at the population level by modeling available data for a subset of the population. Predictive models using multivariable smoothing explained reasonable amounts of variance. Other exposure models with comparable performance have been used successfully in epidemiologic investigations to characterize exposure-outcome associations.

**P01.1850. Oxidative Stress Index Is Increased in Children of Riverside Towns Affected by Industrial Discharges in Central Mexico and Is Inversely Correlated with Metabolite Excretion of VOC**

Rocío López

*4. Centro Fray Julián Gárces, Derechos Humanos, Tlaxcala, Mexico.*

**Abstract:** INTRO The Atoyac River located into Tlaxcala and Puebla states in Mexico, has been classified as highly polluted by environmental authorities, several communities are settled on its banks, affecting around 1.5 million persons, as well as farmland. The river receives waste from industrial discharges, mainly in liquid form, containing a large amount of volatile organic compounds (VOCs), thus giving rise to an environmental distribution of toxics in the area. METHODS To demonstrate that this environment affects important physiological processes that have an impact in health, we conducted a study of schoolchildren from small communities on the banks of the river and in another similar town located far from it. 91 and 93 students (age range: 8-12, no diagnosed chronic disease), were studied from each site for oxidative stress index (OSI) in blood plasma samples, calculated from the total antioxidant capacity and the total oxidative status, BTEX metabolite excretion in urine samples, and relevant metabolic polymorphisms participating in the bioactivation-detoxification of most VOC: CYP2E1 RsaI, NQO1 C609T, and null polymorphisms of GSTT1 and GSTM1. RESULTS OSI was significantly higher in children living by the river ( $5.23 \pm 3.4$  vs  $2.59 \pm 1.46$ , 95% C.I.). At this site, OSI was correlated with diminishing metabolite excretion and a diminished antioxidant capacity; an association with allelic variants of the metabolic polymorphisms of CYP2E1 c2c2, GSTT1 present and NQO1 CC was also observed. CONCLUSIONS The expected health problems for these children as they grow older involves a wide array of disorders, including cancer and fertility risks for them and their children. Protection programs must be designed that include a constant monitoring of early biological effects, at the same time that environmental protection measures are applied to halt the deterioration of fundamental resources for a healthy life.

**P01.1860. Exposure to Heavy Metals and Respiratory Function among E-Waste Burners at Agbogbloshie, Accra**

Afua Asabea Amoabeng

**Abstract:** Background: Dismantling and open air burning of electronic waste (e-waste) results in the release of mixtures of pollutants such as metallic dust, fumes and toxic gases deleterious to human health. Elevated biological and personal ambient air levels of heavy metals have previously been reported among e-waste workers at Agbogbloshie, Accra. Objective: The aim of this preliminary study was to assess the association between levels of heavy metals nickel (Ni) in urine, and lead (Pb) in blood and pulmonary function (Forced Expiratory Volume in one second (FEV1), Forced Vital Capacity (FVC) and ratio of FEV1/FVC) among e-waste recyclers constantly involved in open air burning at Agbogbloshie, Accra. Methods: After ethical approval from the Ministry of Health, and receipt of consent from study participants, 10 ml of venous blood and 20 ml of urine was collected and analysed for Ni and Pb using the Atomic Absorption Spectrometer (PerkinElmer, Pin AAcle 900T, London, UK). Lung function indices (FVC, FEV1, FEV1/FVC) were obtained using a spirometer (Spirolab III, MIR, Italy). Mean values and standard deviations of heavy metals, FVC, FEV1, FEV1/FVC and proportions of respiratory symptoms were computed. Multivariate linear regression analysis was used to assess the associations between heavy metals in blood and urine and respiratory function parameters. Results: The most commonly self-reported respiratory symptoms were sore throat (50%), chest pains (45.5%), excessive phlegm (45.5%), and chronic cough (37%). The Mean concentrations (standard deviation) of the heavy metals were bPb 119.16 µg/L (47.10) and uNi 8.77µg/L (1.26). There was no significant association between the heavy metals and the measures of respiratory functions. Conclusions: This study showed elevated levels of lead and nickel in the blood and urine of the e-waste burners. However, there was no significant association between lung function and the heavy metals.

## **P01.1900. Environmental Contamination from E-Waste Activities: A Systematic Review**

Karel Houessionon

*Karel G. Houessionon<sup>1</sup>, Sylvia A. Takyi<sup>2</sup>, Julius Fobil<sup>2</sup>, Marius Kedote<sup>1</sup>, Benjamin Fayomi<sup>3</sup>, Edgard-Marius Ouendo<sup>1</sup>, Catherine Bouland<sup>4</sup>, Nil Basu<sup>5</sup>*

- 4. Ecole de Santé Publique, Université Libre de Bruxelles, Bruxelles, Belgium.*
- 5. McGill University, Montreal, QC, Canada.*

**Abstract:** Introduction : The recycling of electronic waste (e-waste) contaminates ecosystems and people with a range of pollutants though to our knowledge the matter has yet to be reviewed through a systematic analysis. Methods : A systematic review process was adopted from the Office of Health Assessment and Translation from the U.S. National Toxicology Program. A full literature search on MEDLINE (PubMed) and Web of science was conducted using a priori key words and MeSH terms. The studies selected in this work are those dealing with heavy metals (Cd, Hg, As, Pb and Cr) in two media (soil and water). In total, 59 scientific papers that met the predefined criteria were identified and included in the review. Among others, the information was collected on the design, location of the study, type of heavy metal, and measurement. Until now a narrative synthesis has been conducted on all included studies with future plans to perform an analytical comparison. Results : In general, the literature provides information on the high contamination of soils, agricultural soils, surface water, river, well water, and drinking water by heavy metals. This contamination ranges from recycling sites to residential areas. More than 70% of the studies were conducted in Asia. Conversely, in the African region, only few, (<10%) studies have examined the problem of environmental contamination by heavy metals from e-waste, although several studies show that the problem is growing. Conclusion : Several studies have addressed the issue, but it is imperative to take a holistic approach of the growing e-waste issue. Key words : e-waste, heavy metals, soil, water, environment

## **P01.1910. Association of Low-Level Arsenic Exposure with Academic Achievement in Young Schoolers, a Cross-Sectional Study in Montevideo, Uruguay**

Gauri Desai

*Gauri Desai<sup>1</sup>, Gabriel Barg<sup>5</sup>, Elena I. Queirolo<sup>2</sup>, Marie Vahter<sup>3</sup>, Fabiana Peregalli<sup>2</sup>, Nelly Mañay<sup>4</sup>, Katarzyna Kordas<sup>1</sup>*

- 5. Department of Neurocognition, Catholic University of Uruguay, Montevideo, Uruguay.*

**Abstract:** Background: Arsenic (As) exposure is associated with modest IQ deficits but its relation with children's academic achievement is understudied. Objectives: In this cross-sectional study, we examined the association between low-level As exposure and academic achievement among 5-8 year-old Uruguayan children, and tested for effect modification by As methylation capacity. Methods: We measured total urinary As (UAs) concentrations and the proportion of monomethylarsonic acid (%MMA) in urine of 328 children and assessed academic achievement using six subtests of the standardized Woodcock-Muñoz achievement battery. We tested the association between a continuous UAs measure adjusted for urinary specific gravity and tertiles of achievement subtest scores in ordinal logistic regressions. The models were adjusted for child's sex, BMI for age z scores, serum ferritin, blood lead, hemoglobin, and general intelligence; month of test, tester, mother's education, crowding at home, HOME inventory score, parental smoking, and household possessions. We assessed effect modification with the interaction term between %MMA and UAs, at  $p < 0.05$ . Results: The median UAs was 11.9  $\mu\text{g/l}$  (range = 1.4-93.9) and median %MMA was 9.42 (range=2.6-24.8). Each higher unit of UAs was associated with increased log odds of being in the higher tertile of the scores of three subtests - reading fluency (for low vs. mid and high tertile,  $\beta=0.06$ ; 95%CI: 0.01, 0.11), passage comprehension (for low vs. mid and high tertile,  $\beta=0.06$ ; 95%CI: 0.01, 0.12), and applied problems (for low vs. mid and high tertile,  $\beta=0.05$ ; 95%CI: 0.0001, 0.10) in covariate-adjusted models. We found no evidence of effect modification by %MMA. Conclusion: Scores on the reading fluency, passage comprehension, and applied problems subtests showed weak positive associations with As exposure, which need further examination in larger studies.

## **P01.1930. Blood Lead Is Associated with Latent Subgroups of Cognitive Performance in a Cross-Sectional Study of Uruguayan Children**

Seth Frndak

*Seth Frndak<sup>1</sup>, Gabriel Barg<sup>2</sup>, Elena I. Queirolo<sup>3</sup>, Nelly Mañay<sup>4</sup>, Fabiana Peregalli<sup>3</sup>, Katarzyna Kordas<sup>1</sup>*

*1. School of Public Health and Health Professions, University at Buffalo, Buffalo, NY, United States.*

*2. Department of Neurocognition, Catholic University of Uruguay, Montevideo, Uruguay.*

*3. Center for Research, Catholic University of Uruguay, Montevideo, Uruguay.*

*4. University of the Republic of Uruguay (UDELAR), Toxicology - Faculty of Chemistry, Montevideo, Uruguay.*

**Abstract:** Introduction. Lead exposure, even at low levels, harms child cognition. The effect of lead across individual IQ domains, however, has been inconsistent in the literature. Latent cognitive subpopulations were identified to elucidate effects of lead across several cognitive domains simultaneously. Methods. Among of 357 children 5-8 years old from Montevideo, blood lead levels (BLL) were measured with atomic absorption spectroscopy. Cognitive performance was assessed using 3 tests from the Cambridge Neuropsychological Test Automated Battery (CANTAB): Intra-Extra Dimensional Shift (IED), Spatial Span (SSP) and Stockings of Cambridge (SOC), as well as the Woodcock-Muñoz cognitive battery (WM): Visual-Motor Integration, Verbal Comprehension, Visual-Auditory Comprehension, Concept Formation, Visual Spatial Thinking, Number Inversion and Spatial Relationship test. Bender Gestalt Test was also included. A total of 10 cognitive outcomes, reflecting differing domains of IQ were entered into a latent class analysis (LCA). After extracting cognitive classes, BLL was entered into an ordinal regression predicting cognitive class membership, controlling for socioeconomic and demographic confounders. Results. Mean BLL was 4.15 mg/dL and 31% children had BLL >5 mg/dL. Four latent classes were identified: A "High Performing" class (14%), an "Average" class (54%), a class performing well on SSP, but poorly on WM "Poor WM / Intact Memory" (17%), and a class performing poorly on WM, SOC and IED "Global Cognitive Impairment" (15%). Upper blood lead tertiles were associated with lower odds of membership in the higher performing classes: 2nd tertile OR = 0.50 (0.18, 1.40) and 3rd quintile OR = 0.54 (0.23, 1.25), although this did not reach statistical significance. Conclusions. Even at low concentrations, there is some evidence of a blood lead association with impairment across multiple cognitive domains.

**P01.1940. Sperm Aneuploidy in a Birth Cohort of Faroese Men Exposed in Utero to p,p-DDE and PCBs**

Courtney Irwin

*Courtney Irwin<sup>1</sup>, Karisma Nagarkatti<sup>1</sup>, Heather Young<sup>1</sup>, Pal Weihe<sup>2</sup>, Philippe Grandjean<sup>3</sup>, Laura Neumann<sup>1</sup>, Melissa J. Perry<sup>1</sup>*

*1. Department of Environmental and Occupational Health, George Washington University, Alexandria, VA, United States.*

*2. Department of Occupational Medicine and Public Health, Faroese Hospital System, Tórshavn, Faroe Islands.*

*3. Department of Environmental Health, Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

Abstract: It is known that sperm aneuploidy contributes to early pregnancy losses, and to congenital abnormalities. Although the causes are unknown, environmental contaminants are suspected. Previously published data on 90 Faroese men showed that organochlorine exposure is associated with sperm disomy. Associations based on cord blood samples from a Faroese birth cohort (n=40) was apparent, but not statistically significant. This study aims to evaluate whether a significant association can be detected with a larger sample size. Serum and semen samples were obtained from 22-year-old men (n=100) who belonged in the birth cohort and participated in Faroe Islands health studies from 2009 to 2010. Serum samples were analyzed for p,p-DDE and major PCB congeners (118, 138, 153, and 180) and adjusted for total lipids. Cord blood and age-14 serum were available and were also analyzed for p,p-DDE and PCBs. Sperm fluorescence in situ hybridization (FISH) for chromosomes X, Y, and 18 was used to determine rates of XX18, XY18, YY18, and total disomy. Multivariable adjusted Poisson models (SAS GENMOD procedure) were used to estimate the relationship between organochlorine exposure and sperm disomy outcomes. The Poisson model was fitted using disomy measures (XX18, YY18, XY18, or total sex chromosome disomy) as the outcome variable, the natural logarithm of the number of sperm counted as the offset variable, the organochlorine exposure of interest as the independent variable. Age, abstinence time, smoking status, log of sperm concentration, motility, and morphology were all potential confounders controlled for in the adjusted analysis. Incidence rate ratios (IRRs) and 95% confidence intervals were calculated for each model. Because associations between cord blood concentrations of p,p-DDE and PCBs and sperm disomy in adulthood were not consistently significant in the original 40 men, we hypothesize that the addition of 50 men to this original cohort will yield more consistent results.

**P01.1950. Distribution of Polybrominated Diphenyl Ethers (PBDEs) in Newfoundland Diet: Possible Connection to Hypothyroidism**

Atanu Sarkar

*Nicole Babichuk<sup>1</sup>, Atanu Sarkar<sup>1</sup>, Joseph Bautista<sup>2</sup>, Cora Young<sup>3</sup>, Shree Mulay<sup>1</sup>, John Knight<sup>1</sup>*

*1. Community Health, Memorial University, St. John's, NF, Canada.*

*2. Chemistry, Memorial University, St. John's, NF, Canada. 3. Chemistry, York University, Toronto, ON, Canada.*

Abstract: Newfoundland sits directly in the Gulf of St. Lawrence and receives drainage from the Great Lakes watershed and the St. Lawrence River, both of which are contaminated with polybrominated diphenyl ethers (PBDEs) from anthropogenic sources. PBDEs have been inversely associated with thyroid hormones, and can also bioaccumulate in species to higher trophic levels. Seafood consumption is consistently found to be one of the main pathways for PBDE exposure in humans. The objective of this study is to explore if there may be a risk of human exposure to PBDEs from local seafood consumption in Newfoundland (NL). Liver samples from turbot (*Scophthalmus maximus*) and cod (*Gadus morhua*) were collected off the coasts of NL, and analyzed by gas chromatography/mass spectrometry for PBDE congeners. Residents in Burin (south coast) and New-Wes-Valley (northeast coast) completed a seafood consumption survey and gave blood samples to be tested for thyroid hormone levels and PBDE concentrations. BDEs-28, 47, 99, 156, 209, and methoxylated polybrominated diphenyl ethers 47 (MeO-BDE-47) and 68 (MeO-BDE-68) were detected in fish liver tissue from all sampling locations around NL. Concentrations of  $\Sigma$ PBDEs (5.52-11.75 ng/g) did not differ in concentration coastwise or by species. Results from the seafood consumption survey and human blood samples will be available for the conference. PBDE concentrations in fish liver do not differ by species or location, therefore there may be PBDEs in the Labrador current and from the St. Lawrence River affecting the marine food chain around NL. This study is the first to document PBDE contamination in the Newfoundland coastal waters and population, and adds to past research on health effects of PBDE contamination from the St. Lawrence River. This research will help inform policy development of chemicals use and regulation in Canada, and increase research into environmental contamination and public health.

## **P01.1960. Change in Obesity Prevalence Attributable to Reduction of Sodium Intake in Korean Adults**

Jong-Tae Lee

*Dahyun Baek<sup>1</sup>, Garam Byun<sup>1</sup>, Sooyen Kim<sup>1</sup>, Hyeonjin Song<sup>3</sup>, Sera Kim<sup>1</sup>, Hyomi Kim<sup>1</sup>, Honghyok Kim<sup>1</sup>, Yongsoo Choi<sup>3</sup>, Jong-Tae Lee<sup>2</sup>*

- 2. School of Health Policy and Management, College of Health Science, Korea University, Seoul, Korea (the Republic of).*
- 3. Korea University, Seoul, Korea (the Republic of).*

**Abstract:** Background: Sodium intake is considered to be an important risk factor of obesity. In South Korea, sodium reduction policy has been implemented since 2010. The aim of this study was to identify the relationship between sodium and obesity and to investigate the change in the number of obese patients attributable to sodium intake before and after the policy. Method: This study used Korean National Health and Nutrition Examination Survey, 2007-2016. We applied logistic regressions to examine association between logarithm of daily sodium intake and obesity (BMI  $\geq$  25 kg/m<sup>2</sup>). We adjusted for demographic factors, health behaviors, and socioeconomic status. We calculated odds ratios and annual attributable number of obese patients stratified by gender. Result: The overall prevalence of obesity was 36.16% and 29.38% for men and women, respectively. There was a significant reduction in sodium intake from 2010 to 2016. The odds ratios of obesity per unit increase were 1.259 (95% CI, 1.163-1.362) and 1.068 (95% CI, 1.002-1.138) for men and women, respectively. The number of obese patients attributable for sodium intake was reduced by 7.3 per 1000 people, 2.6 per 1000people in men and women, respectively, since implementation of sodium reduction policy. Conclusion: Our findings suggest that a high sodium intake is associated with increasing risk of obesity. The decrease in the number of obese patients attributable to sodium intake suggests that the sodium reduction policy is effective in reducing obesity.

## **P01.1970. Dietary Persistent Organic Pollutants Exposure, Omega-3 Fatty Acid Intake and Type 2 Diabetes among First Nations in Canada**

Lesya Marushka

*Lesya Marushka<sup>1</sup>, Malek Batal<sup>2</sup>, Tonio Sadik<sup>3</sup>, Harold Schwartz<sup>4</sup>, Amy Ing<sup>2</sup>, Karen Fediuk<sup>5</sup>, Constantine Tikhonov<sup>4</sup>, Laurie Chan<sup>1</sup>*

*5. Dietitian and Nutrition Researcher, Saanich, BC, Canada.*

**Abstract:** The prevalence of type 2 diabetes (T2D) among First Nations (FNs) in Canada is 3 to 5 times higher than that in the general population. Besides lifestyle factors, such as physical inactivity and poor diet, exposure to persistent organic pollutants (POP) was reported to increase the risk of T2D. On the other hand, omega-3 fatty acids (n-3 FA) from fish may have a beneficial effect on T2D. This study aims to investigate the associations between POP exposure and n-3 FA intake from fish with the prevalence of T2D in a nationally representative sample of First Nations in Canada, living on-reserve south of the 60th parallel. Dietary, health and lifestyle data from the First Nations Food Nutrition and Environment Study, a cross-sectional study (2008-2017), were analyzed. The sample consisted of 6094 FNs adults living in 85 communities across Canada. The consumption of locally-harvested fish was estimated with a food frequency questionnaire. Fish samples were analyzed for the presence of POP including dichlorodiphenyldichloroethylene (DDE) and polychlorinated biphenyls (PCBs). Dietary n-3 FA intake was determined using the Canadian Nutrient File. The associations between dietary POP, n-3 FA and self-reported T2D were investigated using multiple logistic regression models adjusted for confounding factors. We will discuss the results in the context of risk-benefit assessment and use the evidence to support the development of dietary advisory associated with POP exposure.

**P01.1980. Study on the Application Effect of School-Family Integrated Intervention Model in Correcting Adolescent Unhealthy Eye Hygiene Habits**

Wenwen Wu

Wenwen Wu<sup>1</sup>, Xiaodong Tan<sup>1</sup>, Yanan Zhang<sup>1</sup>, Xuyu Chen<sup>1</sup>

1. School of health science, Wuhan University, Wuhan, Hubei, China.

**Abstract:** Object: The generation and development of myopia is closely related to the eye hygiene habits. The purpose of this study is to evaluate the effect of school-family integrated intervention on changing adolescent myopia related behaviors. Methods: This was a pretest and posttest quasi-experimental design. A random sampling method was used to select 5564 students in Wuhan, Hubei province (China). Experts in the field of ophthalmology, epidemiology and health management do health education for teachers and parents to introduce correct eye hygiene habits and methods of myopia prevention. Since September 2015, teachers and parents conducted 1 years of supervision and comprehensive intervention on the students' eye hygiene behaviors with guidance of experts. Before and after the experiment, a number of variables related to eye hygiene habits were evaluated. Data were analyzed using independent samples Student's t test and Pearson  $\chi^2$ . Result: The comparison of the variables before and after the intervention showed significant statistical differences. Through intervention, the average time of continuous reading and writing decreased from (1.61±1.01) hours/day to (1.56±1.04) hours/day( $t=3.97, p<0.001$ ), outdoor activity increased from (1.52±0.90) hours/day to (1.77±0.93) hours/day( $t=3.970, p<0.001$ ) and continuous watching TV or cellphone reduced from (1.73±1.31) hours/day to (1.41±1.13) hours/day ( $t=23.54, p<0.001$ ). Moreover, the proportion of student who paid attention to the posture of reading and writing increased from 27.3% to 56.5% ( $\chi^2=974.74, p<0.001$ ), and did overlooking exercise daily increased from 23.8% to 49.7% ( $\chi^2=807.12, p<0.001$ ), and did eye exercise daily increased from 38.8% to 53.3% ( $\chi^2=234.42, p<0.001$ ), and took note of distance between eye and TV or cellphone increased from 46.1% to 57.7% ( $\chi^2=150.22, p<0.001$ ). Conclusion: The school-family integrated intervention model can effectively improve adolescent eye hygiene habits.

**P01.1990. Effects of Lead, Mercury, Manganese and Cadmium Co-Exposure on Preschool Children's Serum BDNF Levels in Taizhou, China**

Cancan Zhou

Abstract: It has been indicated that metals can lead to adverse effects on nervous system in children. Brain derived neurotrophic factor (BDNF) plays an important role in the survival, growth and development of neurons. However, the relationship between blood metal concentrations such as lead (Pb), mercury (Hg), manganese (Mn), cadmium (Cd) and serum BDNF levels was little demonstrated. A total of 574 preschool children (average age of 60 months; 307 boys and 267 girls) living in polluted areas (Taizhou, China) were recruited to participate in this study. Blood Pb, Hg, Mn and Cd levels were determined by the tungsten atomizer absorption spectrophotometer. Serum BDNF levels were determined by ELISA kits. The geometric means of blood Pb, Hg, Mn and Cd levels of all participants were 76.26 µg/L, 1.27 µg/L, 23.96 µg/L and 0.28 µg/L respectively. The Serum BDNF levels of girls was significantly high than that of boys ( $P < 0.01$ ). After adjusting confounders, general liner model showed that only blood Cd levels had a significant negative association with serum BDNF levels ( $\beta = -0.03$ , 95% CI: -0.05--0.01). Serum BDNF levels were significantly negative association with blood Mn and Cd levels for girls, but not for boys ( $\beta = -0.142$ , 95% CI: -0.282--0.002;  $\beta = -0.041$ , 95% CI: -0.073--0.009). Furthermore, significant positive correlation between blood Mn and blood Cd levels ( $P < 0.0001$ ) and positive interaction between blood Mn and Cd levels on serum BDNF were observed ( $\beta = -0.11$ , 95% CI: -0.17--0.05). This study suggest a negative association between elevated Cd exposure and serum BDNF levels. Elevated Cd, Mn exposure presenting more pronounced effects on girls. Cd and Mn may have interactive adverse effects on nervous system in children.

## **P01.2000. Investigating Health-Relevant Air Pollution Concentration Linkages across Multiple Seasons during Indoor Cookstove Campaign in Rural India**

Julian Marshall

**Abstract:** Biomass combustion in residential cookstoves is a major source of air pollution and a large contributor to the global burden of disease. Carbon financing offers a potential funding source for health-relevant energy technologies in developing countries. We conducted a randomized intervention study to evaluate air pollution impacts of a carbon finance-approved cookstove intervention in rural South India. Prior research on this topic often has used time-integrated measures of indoor air quality. Here, we employed real-time monitors, thereby allowing investigation of diurnal and hourly trends in concentrations. We measured 24h indoor concentrations of fine particulate matter (PM<sub>2.5</sub>), black carbon (BC) and carbon monoxide (CO) in intervention households (used newer, rocket-type stoves) and control households ("nonintervention"; continued using traditional open fire stoves). We conducted "per protocol" versus "intent to treat" analyses, and compared 24h averages of air pollutants versus cooking hours only averages. Cookstoves were associated with non-significant reductions in CO (1.5 ppm,  $p=0.28$ ) and PM<sub>2.5</sub> (148  $\mu\text{g}/\text{m}^3$ ,  $p=0.46$ ) but increased BC concentration (39  $\mu\text{g}/\text{m}^3$ ,  $p<0.05$ ) and the ratio of BC/PM<sub>2.5</sub> (25%,  $p<0.05$ ) during cooking-relevant hours-of-day relative to controls. Calculated median effective air exchange rates based on decay in CO concentrations were stable between seasons (season 1: 2.5 h<sup>-1</sup>, season 2: 2.8 h<sup>-1</sup>).

**P01.2010. In Search of Preventive Measures for Reducing Lead Exposure in Children Who Live in Lead Smelter and Mining Communities**

Landon MacGillivray

Abstract: Environmental lead exposure even at low levels may result in persistent, long-term neuro-developmental adverse effects in young children. Extensive literature has demonstrated childhood lead exposure results in a decrease in intelligence quotient (IQ) points. There is no known safe blood lead level (BLL) and poor outcomes are associated with BLLs as low as 1-2 µg/dL. In communities adjacent to active smelters or mines, such as Trail, British Columbia, a continuous source of environmental lead exposure exists and implementation of preventive measures is vital. Our objective was to evaluate the effectiveness of different strategies and preventive measures utilized in communities adjacent to mining or smelter operations to mitigate environmental lead contamination. We conducted a literature review and summarized our findings in a report using Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) Guidelines. We compared the type of proposed interventions in the scientific literature with the current interventions already implemented in Trail. Then based on considerations surrounding the effectiveness of each intervention, we proposed additional interventions to complement current efforts in Trail. In communities with active lead smelter and mining operations, stack and fugitive emission reductions via governmental policy changes, technology advancement or plant closure have far superior outcomes compared to other preventive measures. Multifactorial approaches are also necessary to manage ongoing lead exposure. In Trail, fugitive dust emissions are identified as the primary source of environmental lead contamination. With significant collaborative efforts in recent years, a multitude of measures have been implemented in Trail, to minimize potential risk of ongoing contamination. We hope our findings will help this collaborative effort to further enhance interventions and take into consideration other possible approaches proposed in our report.

## **P01.2020. Predictors of Urinary Phenol and Paraben Concentrations among Pregnant Women in Northern Puerto Rico**

Pahriya Ashrap

**Abstract:** In light of potential health impacts associated with phenol and paraben exposure, targeted action for the elimination or reduction of exposure sources may be warranted. However, little is known regarding important sources and pathways of exposure. This is particularly important in areas such as Puerto Rico, where residents have higher exposures to many of these chemicals, as well as higher rates of many adverse health outcomes, compared to the mainland US. The objective of this study was to determine concentrations and predictors of urinary phenol and paraben biomarkers measured at multiple times during pregnancy among women living in Northern Puerto Rico. We recruited 1003 pregnant women from prenatal clinics and collected urine samples and questionnaire data at up to three separate visits between 16 to 28 weeks gestation. Urine samples were analyzed for eight phenols and four parabens: 2,4-dichlorophenol (24-DCP), 2,5-dichlorophenol (25-DCP), benzophenone-3 (BP-3), bisphenol A (BPA), bisphenol S (BPS), bisphenol F (BPF), triclosan (TCS), triclocarban (TCC), butyl paraben (B-PB), ethyl paraben (E-PB), methyl paraben (M-PB), and propyl paraben (P-PB). Detectable biomarker concentrations among pregnant women was prevalent and tended to be higher than those measured in women of reproductive age from the general US population. A decreasing temporal trend was statistically significant for urine concentrations of BPA, while BPS showed an increasing temporal trend. We found significant positive associations between biomarker concentrations with self-reported use of products. There was an increasing trend of TCC/TCS concentrations with increased concentrations of TCC/TCS listed as the active ingredient in the bar soap/liquid soap products that were reported being used. Our results suggest several potentially important exposure sources to phenols and parabens in this population and can inform targeted approaches to reduce exposure to these chemicals or their precursors.

## **P01.2030. An Effect of Maternal Secondhand Smoke Exposure at Early Pregnancy on Autistic Behaviors at 5 Years of Age**

Hyunjoo Joo

**Abstract:** Autism Spectrum Disorders is a syndrome with multiple causes and different mechanisms leading to abnormal development. Only a few longitudinal studies have investigated the association between maternal SHS exposure and autistic behaviors. We examined the effect of Secondhand Smoke exposure on the autistic behaviors in children at 5 years to identify the sensitive time window of exposure considering potential gender difference. A total of 1,751 pregnant women and children participated in the prospective birth cohort study, Mothers and Children's Health study since 2006. Information concerning SHS exposure was obtained from the children's parents or guardians by means of a self-administered questionnaire that included a set of standardized questions commonly used in previous studies. A total of 458 children at 5 years were assessed for behavior by using the Social Responsiveness Scale (SRS). The association between SHS exposure at each time window and autistic behaviors was examined using generalized linear model adjusted for maternal age at pregnancy, maternal educational level, household income, household income, residential area, parity and early blood lead. SHS exposure at early pregnancy was significantly associated risk of autistic behaviors in boys while it was not at postnatal periods: for SHS in early pregnancy, score of Total - SRS increased by 2.66(95% CI 0.06, 5.26) in boys, in which the interaction effect of gender was significant ( $p$ -interaction: 0.01). However, the SHS exposure at any time did not show a significant association with autistic behaviors in girls. SHS exposure on children's autistic behavior at 5 years showed a susceptible exposure time window of early fetal period in boys. SHS exposure did not show an association with autistic behaviors in girls.

**P01.2040. Trace Metal Exposure and Health Effects among Urban Children Living in Areas with Different Degrees of Pollution in Lubumbashi, DR Congo**

Abstract: Lubumbashi is the capital city of the (former) Katanga province in DR Congo and hosts many copper-cobalt mines and refining plants that are past and current sources of pollution. We investigated trace metal exposure and possible respiratory health effects among children living in two urban neighbourhoods with different degrees of pollution. During two campaigns conducted in August 2012 (dry season) and January 2013 (rainy season), we recruited children (9-13 y) in Tshamilemba, close to a metal refinery (n=199), and in Maramba, taken as a control area (n=170). We administered a respiratory questionnaire, gave diaries for recording symptoms during two weeks, and performed spirometry. Concentrations of 25 trace metals were measured by inductive coupled plasma - mass spectrometry in spot samples of urine. Metals were also measured in local well waters. Airborne particulate matter (PM10) was collected by static air sampling pumps. Mean PM10 was 121 µg/m<sup>3</sup> and 103 µg/m<sup>3</sup> in Tshamilemba and Maramba, respectively. Geometric mean (GM, with IQR) concentrations (µg/L) of cobalt in well water were 10-fold higher in Tshamilemba [8 (0.1-2632)] than Maramba [0.8 (0.1-3.9)]. GM (IQR) urinary concentrations (µg/g creatinine) of cobalt were higher in Tshamilemba [dry season 16.5 (6.9-29.0); rainy season 20.2 (10.3-33.0)] than Maramba [4.1 (1.8-9.8); 11.9 (5.0-20.1)]. Prevalence of cough during the two weeks of observation was higher in Tshamilemba (13%) than in Maramba (1%), but other symptoms (eyes, skin, wheezing, dyspnea) did not differ. The groups did not differ significantly in pulmonary function indices. In this cross-sectional study, we found evidence of higher exposure to trace metals, especially cobalt, in Tshamilemba than Maramba, but apart from a higher prevalence of cough in Tshamilemba, no other differences in respiratory health were found between the more highly exposed children and the control children.

## **P01.2050. Spatial and Temporal Variability of Soil Metal Contaminants in the Animas and San Juan Watershed Downstream from Legacy Mining**

Gaurav Jha

*Gaurav Jha<sup>1</sup>, April Ulery<sup>1</sup>, Kevin Lombard<sup>1</sup>*

*1. Plant and Environmental Sciences, NEW MEXICO STATE UNIVERSITY, Las Cruces, NM, United States.*

**Abstract:** On August 5, 2015, three million gallons of acidic, metal-laden water was accidentally released into the Animas River from the Gold King Mine (GKM) in Silverton, Colorado. The majority of contamination released by the GKM spill existed mainly as suspended solids likely deposited within the streambed sediment of the Animas and San Juan Rivers, as well as in irrigation ditches that could not be closed ahead of the arrival of the contaminated plume. While contamination from this one event may not have reached the closed irrigation ditches and fields, legacy mining that may have released metals into the watershed over the last 150 years may have accumulated in the soils. The goal of this project is to determine the concentration of metals in agricultural fields and irrigation ditches across the Animas watershed. The concentration of 9 heavy metals (Al, As, Pb, Cu, Cr, Ca, Mn, Zn, Fe) are determined using the Portable X-Ray fluorescence in irrigation ditches, three different vegetations of agricultural fields (soil and plant samples). The average concentration of As exceeded the guideline value (7.07 ppm) specified by NMED at certain hotspots identified for pasture (7.19 ppm), alfalfa (6.92 ppm) and vegetable (7.13 ppm) fields. On observing the exceedances at areas close to the irrigation sources plant samples were collected in four quadrants in a gradient of irrigation water flow in the field. The concentration range of As in plant tissue for pasture (0.89-1.25 ppm, n = 12), alfalfa (0.94-1.11 ppm, n = 12) and vegetable (0.5-0.9 ppm, n = 24) fields were below the guideline value of 1.7 ppm (Kabata-Pendias, 2011). The higher concentrations of arsenic and manganese that were found in some hotspots did not correlate to increased concentration of metal uptake in plants. The ongoing research for another season will help the people in Navajo Nation to make decisions about the safety of the soils to resume the ceremonial uses of soil and the cultivation of agricultural crops.

## **P01.2060. Exposure of Inorganic Mercury in the General Population and Ethnic Minorities in New York City and Its Associations with Skin Lightening Practice**

Chi Wen

*Chi Wen<sup>1</sup>, Emma K. Benn<sup>1</sup>, Richa Deshpande<sup>1</sup>, Bian Liu<sup>1</sup>*

*1. Department of Population Health Science and Policy, Icahn School of Medicine at Mount Sinai, New York, NY, United States.*

Abstract: Skin lightening practice (SLP) was identified as a source of inorganic mercury exposure among Caribbeanborn blacks and Dominicans, who had geometric mean urine mercury concentration ([GMuHg])  $\geq 1$  ng/ml compared to 0.69 ng/ml among the general population in the 2004 New York City Health and Nutrition Examination Survey (NYC HANES). We assessed such a pattern using the 2013-2014 HANES (n=1408), which also asked about the usage of skin lightening cream in the past 30 days. In addition, we present the preliminary results from a pilot study on SLP among NYC women of African and Afro-Caribbean ancestries (n=74) who have been bleaching their skin for a year. The population-weighted SLP prevalence was 5.5% overall and 8.1% among the Caribbean population (n=355). The overall [GMuHg] and its 95th percentile was 0.37 and 1.7 ng/ml, similar to the levels found among subgroups such as participants with SLP, the Caribbean population, or the Caribbean participants with SLP. Among those with SLP (n=75), 70% were female, 37% were Hispanic, 36% were Caribbean, and their [uHg] ranged from 0.063 ng/ml to 11ng/ml. Significant factors ( $p < 0.05$ ) associated with [uHg] were being non-US born, higher family income ( $\geq \$100,000$ ), having silver-colored dental fillings and frequent fish or shellfish consumption ( $\geq 3$  times in the past 30 days). In our pilot study, 81% participants were non-US born, about 50% from Jamaica or the Ivory Coast, 89% reported more than 3 years of SLP, 77% used daily, and 12% used while pregnant/breastfeeding. We observed an overall decrease in the population level [GMuHg] in NYC compared to the previous study, and did not find elevated [GMuHg] among the Caribbean or SLP population. Our SLP-focused pilot study showed that SLP is a habitual practice, and the existence of prenatal and postnatal exposures related to SLP may warrant further investigation especially among vulnerable subgroups (e.g., Jamaicans and West Africans) where SLP is more prevalent.

## **P01.2070. Does Overall Environmental Quality Affect End-Stage Renal Disease Survival?**

Marissa Kosnik

*Marissa Kosnik<sup>1</sup>, David Reif<sup>2</sup>, Danelle Lobdell<sup>3</sup>, Thomas Astell-Burt<sup>4</sup>, Xiaoqi Feng<sup>4</sup>, John D. Hader<sup>5</sup>, Jane Hoppin<sup>6</sup>*

**Abstract:** Prevalence of end-stage renal disease (ESRD) in the U.S. increased by 74% from 2000 to 2013, with a 5-year survival of only 42%. To investigate associations between environmental quality and ESRD survival time, we used the Environmental Quality Index (EQI), an aggregate measure of ambient environmental quality at a county level across the U.S., composed of five domains (air, water, land, built, and sociodemographic). Associations between EQI and survival time for 1,091,742 people with ESRD (18y or older and without changes in county residence) from the US Renal Data System were evaluated using proportional-hazards models adjusting for sex, race, age at first ESRD service date, body mass index, alcohol and tobacco use post ESRD diagnosis, and rurality. The models compared the overall EQI percentiles [0-5), [5-20), [20-40), [40-60), [60-80), [80-95), and [95-100], where lower percentiles are interpreted as better EQI. Stratification of findings by age and distance from nearest hospital were examined. >50% of people lived in the two worst (i.e. highest) EQI percentiles. In the full model, there was no consistent direction of association across EQI strata. While age was a significant predictor of survival (Hazard Ratio, 4.27; 95% Confidence Interval, 4.21-4.33 for people > 65 vs. people < 40), there was no evidence of age-specific association with EQI. When considering distance from the nearest hospital, those living ≤10 miles had increased survival in the worst EQI strata (median survival 3.0 vs. 3.5 years for best vs. worst EQI, respectively); however, for people living >20 miles from a hospital, median survival was higher in the best (4.2) vs worst (3.4) EQI. This association held across different rural/urban categories and age groups. While studies have reported associations between EQI and many health outcomes, additional factors should be considered for modeling ESRD survival. This abstract does not reflect EPA policy.

## **P01.2080. Social Environment Change and Social Health Outcomes**

Yanan Zhang

*Yanan Zhang<sup>1</sup>, Xiaodong Tan<sup>1</sup>*

*1. School of Health Sciences, Wuhan University, Wuhan, China.*

**Abstract:** Background: In 2012, 12.6 million deaths globally were attributable to the environment. When accounting for both death and disability, the fraction of the global burden of disease due to the environment is 22% (95% CI: 13-32%). Deaths from environment risks could be prevented, if environmental risks were removed. Objectives: This study aims to share information on the practice and explain the effects of social environment change on social health outcome, based on CDC and community health service center data from a district in Wuhan, China. Methods: A Health in all polices based city practice was conducted in one of the district in Wuhan. Statistical analysis were conducted in SPSS, data were estimated using comparative risk assessment (CRA) method. Results: 1) the health outcomes improved markedly, such as residents' life expectancy has risen to 80.23 years from 79.22 years, maternal mortality per 100,000 newborns has decreased to 10.29 from 11.12, infant mortality rate per 1,000 infants has decreased to 3.80 from 4.78 and children under 5 mortality rate has decreased from 6.89% to 4.42% during three years exploring; 2) the effects of social environment change on medical institutions' medical expenses indicated that the growth rate of residents' medical expenses of residents has slowed down, and the number of hospital patients admissions and hospital days has also decreased. Conclusions: We concluded that three years' social environment change yielded positive effects on the health outcomes of the population, and controlling growth of medical expenses.

**P01.2100. Health-Related Needs Assessment of Artisanal Small-Scale Goldminers in Kadoma/Zimbabwe: Paving the Way for Health Improving Interventions**

Jana Becker

*Jana Becker<sup>2</sup>, Peter Furu<sup>1</sup>, Josephine Singo<sup>3</sup>, Dennis Shoko<sup>4</sup>, Stephan Bose-O'Reilly<sup>2</sup>, Nadine Steckling<sup>2</sup>*

Abstract: Background: Small-scale miners are responsible for over 50 % of the Zimbabwean gold production. However, the sector is characterised by high labour-intensity, low productivity and capital and outdated technologies. Sustainable health interventions are necessary. Objective: The objective of the project was the empirical identification of miners' health needs and corresponding effective, sustainable, and successful future health interventions. Methods: In a two-week field study in Kadoma, Zimbabwe, in late 2017 a health needs assessment was done to determine the miners' needs by applying a mixed methods approach. This included qualitative and quantitative interviews with individuals, group interviews, focus group discussions and observations. Results: A total of 89 miners and 4 health care workers participated in the project. Six main themes with potential for improving miners' health were identified: living conditions, nutrition/hygiene; safe work environment/mining processes; financial support; health care services; education. Especially the need for formalisation and funding as well as low importance of certain interventions to miners are obstacles to sustainable health interventions. Formalisation can only be successful, if the miners' perceptions of governmental involvement are considered and if the reluctance of failed formalisation attempts can be overcome. As the underlying basis for all these approaches, an increase in knowledge and awareness of miners is needed, especially by considering the growing numbers of miners. Conclusion: By taking into account the possible health impacts, the feasibility of interventions, the importance for miners, and their willingness to adapt, interventions aiming at increasing the knowledge and awareness of miners have been identified as most promising for sustainable occupational health. Funding by the German Federal Ministry for the Environment, Nature Conservation, Building and Nuclear Safety is gratefully acknowledged.

## P01. Prenatal and Early Life Exposures and Effects 1

### **P01.2110. Impact of Mercury Exposure on Health-Related Quality of Life during Pregnancy in Suriname**

Anisma Gokoel

*Anisma R. Gokoel<sup>1</sup>, Lois L. Kaersenhout<sup>3</sup>, Ashna Hindori-Mohangoo<sup>2</sup>, M. Sigrid Mac Donald - Ottevanger<sup>1</sup>, Cornelis Zijlmans<sup>1</sup>, Maureen Y. Lichtveld<sup>4</sup>, Emily W. Harville<sup>4</sup>*

**Abstract:** Background: The abundant use of mercury in illegal gold mining in Suriname's interior is of growing concern. The Caribbean Consortium for Research in Environmental and Occupational Health is assessing exposure to Hg in pregnant women and their offspring. This study evaluated the association between Hg levels, perceived health and Health-Related Quality of Life (HRQoL) in Surinamese pregnant women. Methods: Data of 311 pregnant women were analyzed using standardized questionnaires completed during early pregnancy. HRQoL was assessed using seven out of eight scales from the Rand SF-36: physical functioning, role physical, bodily pain, vitality, general health, role emotional and mental health (high scores indicates good health). Perceived health was measured with a 5-point Likert scale. The association among Hg, perceived health, and HRQoL were assessed with adjustment for maternal sociodemographic factors. Results: 83 women (26.7%) had elevated Hg levels that exceeded the USEPA action level (1.1 µg/g); no significant association was observed with perceived health and HRQoL. 75.9% of the women with elevated mercury levels had a good perceived health, compared with 71.1% of the women with normal Hg levels ( $p=0.47$ ). Perceived health was significantly associated with each HRQoL scale ( $p<0.01$ ). For each scale higher mean scale scores were observed among women with elevated Hg levels, except for vitality and mental health; Cohen's effect sizes were small (0.04-0.11). Bivariate analyses showed a borderline association between education (secondary or lower vs. higher) and perceived health (OR: 2.0; 95%CI: 0.95-4.08); and region (interior vs. else) and perceived health (OR: 3.4; 95%CI: 0.90-13.0). Conclusion: One out of four pregnant Surinamese women had hair Hg levels above the USEPA action level; these were not associated with lower HRQoL scores and poor perceived health during early pregnancy. Funding: FIC/NIH U01TW010087-01, U2RTW010104

## **P01.2120. Association between Phenols and Parabens with Gestational Age, and the Modifying Effect of Life Events during Pregnancy**

**Abstract:** Background: Exposure to phenols and parabens, as well as positive and negative life events, have been associated with adverse birth outcomes. However, no studies have looked at the combined effect of these environmental chemicals and life events on birth outcomes. We examined the associations of these environmental chemicals and the Life Events Score (LES) in 922 pregnant women in a cohort of pregnant women in Puerto Rico. Methods: Urinary phenols and parabens were measured at three time points in pregnancy (visit 1: 16-20 weeks, visit 2: 20-24 weeks and visit 3: 24-28 weeks gestation). LES was calculated via a questionnaire at visit 2. Multiple linear regression (MLR) models were constructed to regress gestational age against each of the average levels of phenols and parabens. An interaction term between each chemical and LES was included in the MLR models. All results were transformed into the change in the number of gestational days for an inter-quartile-range difference in the exposure ( $\Delta$ ). Results: The average benzophenone-3, methyl- and propylparaben levels were associated with a 1-2 day increase in gestational age [( $\Delta$  1.90; 95% CI: 0.54, 3.26); ( $\Delta$  1.63; 95% CI: 0.37, 2.89); ( $\Delta$  2.06; 95% CI: 0.63, 3.48), respectively]. TCC was associated with a suggestive 2 day decrease in gestational age ( $\Delta$  -1.96; 95% CI: -4.11, 0.19). The interaction terms between LES and bisphenol-S, bisphenol-F, triclocarban, ethyl- and propylparaben had p values < 0.05. Among these with a significant interaction, LES scores below -1 were associated with 0.5-4 day decrease in gestational age, except for propylparaben, which was associated with a 3 day increase in gestational age. This was driven by a lack of positive events, rather an excess of negative events. Conclusion: BP-3, MPB and PPB were associated with an increase in gestational age. LES modified the association between some chemicals and gestational age. Further studies are required to substantiate these findings.

## **P01.2121. Early-Life Infections, Immune Dysregulation, and Childhood Acute Lymphocytic Leukemia in Costa Rica**

**Abstract:** Introduction: Despite the high incidence of leukemia in Hispanic children, few studies have examined the role of early immune stimulation in the etiology of leukemia in this high-risk population. Methods: We used data from a population-based retrospective case-control study conducted in Costa Rica (2001-2003) to examine the role of early-life infections and immune dysregulation on leukemia incidence among Hispanic children. Cases of ALL (n=239) were diagnosed in 1995-2000 (age <15 years at diagnosis) and were identified through the National Cancer Registry and National Children's Hospital. Population controls (n=579) were frequency-matched to cases by birth year and drawn from the National Birth Registry. Surrogate measures of early immune stimulation were collected through home interviews. Unconditional logistic regression models were adjusted for birth year, sex, and socioeconomic status. Results: Daycare attendance, contact with any pet or farm animal, and a complete vaccination scheme were inversely associated with odds of ALL (OR=0.67, 95% CI: 0.47-0.95; OR=0.39, 95% CI: 0.26-0.59; OR=0.35, 95% CI: 0.18-0.67; respectively). In contrast, experiencing a fever longer than one week (censored in the year prior to diagnosis) was positively associated with ALL (OR=2.53, 95% CI: 1.66-3.85). Breastfeeding, birth order, primary infections, and hospitalizations were not significantly associated with risk of childhood leukemia. Conclusion: Our findings are consistent with the epidemiology of childhood leukemia in non-Hispanic populations and provide additional support for Greaves hypothesis that exposure to infectious agents in early childhood is a protective factor. The observation that having a fever longer than a week increases risk supports an emerging theory that an abnormally strong immune response to infection increases susceptibility to leukemia.

**P01.2130. Urinary Concentrations of Bisphenol-F and Their Associations with Environmental Factors of Pregnant Women: The Mother and Kids Environmental Health (MAKE) Study**

**Abstract:** Background/Aim Bisphenol-F(BPF) is a substitute substances of bisphenol-A and the manufacturing of plastics and epoxy resins(such as food contact materials, structural adhesive). However, the exposure of BPF in pregnant women is presently unknown. This study aimed to examine urinary BPF concentrations of pregnant women and investigate their associations with environmental factors. Methods In order to find out the association with BPF and environmental factors, we plan to recruit more than 300 women during 2nd and 3rd stage pregnancy between 2017 and 2019 in the Korean pregnant women. We also collected information on birth outcome, socio-economic status, use of disposable foods, and consumption habits of consumer products. Multiple regression analysis was performed to assess the effect of BPF exposure by environmental factors. Results The creatinine-adjusted geometric mean of BPF were 0.2 $\mu$ g (95% CI: 0.40-5.49) and that was tended to increase of environmental factors. There were significant associations was observed between BPF and use of plastic cooking tools ( $\beta$ =0.88,  $p$ =0.006), intake of wrapping food ( $\beta$ =0.7,  $p$ =0.05), habits of using perfume ( $\beta$ =0.69,  $p$ =0.05), respectively. None of the BPF concentrations were associated with the other consumer products and food. In addition, we found the associations with BPF and renovation of the house within the last 6 months ( $\beta$ =0.97,  $p$ =0.02). Conclusions We expect this study to provide evidence to support the hypothesis that the environmental factor has an effect on the exposure during pregnancy.

## **P01.2150. Prenatal Persistent Halogenated EDCs and Gestational Glucose Levels in a Racially Diverse Pregnancy Cohort of Overweight Women**

**Abstract:** Background: Animal and human studies suggest certain endocrine disrupting chemicals (EDCs) affect glucose regulation; however, the impact of these chemicals during pregnancy on maternal glucose levels and gestational diabetes (GD) risk has been sparsely examined. Objective: To examine the role of prenatal EDC exposure on fasting plasma glucose (FPG) and GD during pregnancy in overweight women. Methods: A racially diverse, low-income cohort of 103 overweight pregnant women participated in a healthy weight gain behavioral intervention. Single serum measurements of poly- and perfluoroalkyl substances (PFASs), polybrominated diphenyl ethers (PBDEs), and polychlorinated biphenyls (PCBs), and FPG (collected via a fasting blood draw) were taken at late first or second trimester. Physician-diagnosis of GD was determined through medical chart abstraction. We used generalized linear models to assess cross-sectional associations between exposure to EDCs and FPG, and logistic regression to examine associations with incidence of GD after adjusting for age, race/ethnicity, BMI, education, and gestational age at blood draw. Results: The mean FPG was  $4.43 \pm 0.39$  mmol/L. GD or a FPG  $\geq 5.1$  mmol/L was seen in 11.7% of women. A twofold increase of PCB-138 and PCB-153 were associated with 8.17% (95% CI: 1.02, 15.82) and 11.38% (95% CI: 0.65, 23.25) increase in FPG, respectively. A doubling of PBDE-153 significantly decreased FPG by 6.82% (95% CI: -12.50, -0.78). A doubling of PFNA and PFOS was associated with decreased FPG (-8.87% [95% CI: -17.57, 0.76], and -8.50% [95% CI: -16.71, 0.52], respectively). Persistent EDC exposure was not associated with GD or FPG  $\geq 5.1$  mmol/L. Discussion: Preliminary analyses suggest prenatal PCB exposure is associated with higher FPG among pregnant overweight women, whereas certain PBDEs and PFASs were inversely associated with FPG. Further analysis will account for EDC mixtures and repeated measures of FPG across pregnancy and postpartum.

**Abstract:** As part of the African 'Copperbelt', Southern Katanga (DR Congo) has been an area of intensive mining, resulting in widespread environmental contamination. This study was initiated to address concerns about the possible causation of birth defects by toxic metals. Neonates born with a visible birth defect (cases) were recruited by systematic reporting in Lubumbashi for 2 years; controls were normal neonates from the same maternity. Within 1 day after delivery, mothers were interviewed about medical/obstetrical history, socio-economic variables, personal habits, residence and occupation. Trace metals were measured by ICP-MS in maternal urine and venous blood, umbilical cord blood and placental tissue. Congenital malformations were characterized clinically and photographs. Associations between congenital malformations and metal concentrations and variables obtained from the questionnaire are being analysed by multivariate analysis. Overall, 138 cases and 108 controls were included. The two groups were well-matched with regard to potential confounders (maternal age, parity, socio-economic status). Mining-related jobs were more prevalent ( $p < 0.05$ ) among fathers of cases (17%) than controls (8%). In both cases and controls, trace metals in urine and blood were substantially higher than reference values from industrially developed countries. In preliminary analyses, manganese (Mn) appeared significantly higher in cord blood and placental tissue (fetal side) from cases. This is the first study to investigate the association between environmental pollution by mining-related activities and birth defects in sub-Saharan Africa. Preliminary analyses suggest father's work in mining and prenatal Mn exposure are associated with the occurrence of congenital malformations. Limitations of our study include a possible over-matching of cases and controls (controls were born in the same maternity as cases) and that biomonitoring data were obtained at delivery and not early in pregnancy.

## **P01.2170. Indoor Pesticide Exposure, Birthweight, and Gestational Age: A Cohort Study among Pregnant Women in Beijing, China**

**Abstract:** Background: Prenatal exposure to pesticides are a major public health concern for adverse reproductive outcomes including birthweight. The association between pesticide exposure in pregnant women and fetal growth remains inconsistent. Objective: The aim of the present study was to evaluate the association between maternal exposure to indoor pesticides with infant birthweight and gestational age in a Chinese population. Methods: A total of 201 study participants in early pregnancy were recruited from Hangtian and Anzhen Hospitals in the Haidan District of Beijing, China. A baseline questionnaire collected information on demographics, disease history, occupational exposure and medical history. Mothers were asked if they use pesticides/insecticides in the home (yes/no). At follow-up, women reported the birthweight in grams and gestational age in weeks. We used linear regression to estimate the change in birthweight and gestational age related to reported indoor pesticide use. Results: Of the 201 participants, 114 women had information available for both indoor pesticide use and birth outcomes. A total of 19 participants (16.67%) reported indoor pesticide use during the 1st trimester. Birthweight ranged from 1100g-4600g and gestational age ranged from 29-41 weeks. The crude model showed a significant reduced birthweight for mothers exposed to indoor pesticides ( $\beta = -273.37$ ,  $p=0.04$ ). However, after adjustment for parity, smoking status, BMI, and maternal age, we observed no significant association between indoor pesticide use and birthweight ( $\beta = -248.71$ ,  $p=0.06$ ). Indoor pesticide use in the 1st trimester was associated with a significant decreased gestational age ( $\beta = -0.91$ ,  $p=0.04$ ) after adjustment for parity, infant sex, BMI, maternal age, and smoking status. Conclusions: Our results indicate that exposure to home pesticides use during the 1st trimester of pregnancy was associated with a decrease in birthweight and gestational age in this Chinese population.

## **P01.2180. Maternal Urinary Phthalate Concentrations, Gestational Diabetes, and Glucose Intolerance during Pregnancy**

**Abstract:** Background/Aim: Recent studies have linked phthalates, among other endocrine disrupting chemicals, with type 2 diabetes. However, limited research exists on the potential association between phthalates and gestational diabetes (GDM) or impaired glucose tolerance (IGT), defined as a failed glucose challenge test but normal glucose tolerance test, during pregnancy. Methods: We evaluated 11 urinary phthalate metabolites from the first (T1) and third (T3) trimesters of pregnancy and medical record abstraction data in 674 women from The Infant Development and Environment Study. We used logistic regression to examine the associations between log-transformed and specific gravidity adjusted T1-only and average phthalate metabolite concentrations across pregnancy (mean of T1 and T3) with GDM and IGT. We adjusted for maternal age, maternal body mass index, study center, race/ethnicity, and parity. Results: We observed 58 cases of GDM and 66 cases of IGT within the cohort. Average mEP across pregnancy was associated with increased risk of GDM (OR: 1.94; CI: 1.12, 3.39). Other models suggested possible associations of other phthalate metabolites with GDM and IGT but were not statistically significant in the final analysis. Conclusions: Average mEP across pregnancy was associated with increased risk of GDM in this prospective cohort study. Given the prevalence of phthalate exposures and the growing evidence of their potential metabolic effects, future studies should examine this question in larger cohorts of pregnant women, particularly those who may be at higher risk for GDM and IGT.

**P01.2190. Vaginal Douching as a Possible Source of 1,4-Dichlorobenzene among Reproductive-Aged Women: National Health and Nutrition Examination Survey 2001-2004**

Ning Ding

*Ning Ding<sup>1</sup>, Xin Wang<sup>1</sup>, Stuart Batterman<sup>1</sup>, SungKyun Park<sup>1</sup>*

*1. Epidemiology, University of Michigan, Ann Arbor, MI, United States.*

Abstract: Chronic exposure to volatile organic compounds (VOCs) contributes to adverse health effects in humans. No previous study has examined the use of feminine hygiene product as a potential source of VOCs. Several scientists and interest groups are calling for more research to fill in the gaps. Data on 2,432 women aged 20-49 years from NHANES 2001-2004 were used. We examined the associations between self-reported use of feminine products (tampons, sanitary napkins, vaginal douches, feminine spray, feminine powder, feminine wipes/towelettes, and other products) with whole blood concentrations of VOCs. Concentrations were log-transformed to ensure normality. We utilized a directed acyclic graph to identify a minimal adjustment set to account for confounding. Multivariate linear regression models with complex survey design were used to estimate percent changes in VOC concentrations and 95% confidence interval (CI). Black women had a significantly more use of vaginal douching, and significantly higher whole blood concentrations of 1,4-dichlorobenzene ( $P < .0001$ ). After adjusting for age, race/ethnicity, educational attainment, income-to-poverty ratio, body mass index, pregnancy status, and menopausal status, we observed a dose-response relationship between a frequency of vaginal douching in the past 6 months and 1,4-dichlorobenzene ( $P\text{-trend} = 0.04$ ). Compared to never users, women with occasional use ( $\geq 1/\text{month}$ ) of vaginal douching had 18.1% (95%CI: -12.0%, 58.7%) higher concentrations, and those with frequent use ( $\geq 2/\text{month}$ ) had 81.0% (95%CI: 2.2%, 220.8%) higher concentrations of 1,4-dichlorobenzene. Use of feminine powder in the past month was also significantly associated with 35.6% (95%CI: 0.4%, 83.2%) higher concentrations of ethylbenzene. The presence of environmental chemicals contained in feminine hygiene products warrants further examination with longitudinal designs and repeatedly-collected samples.

## **P01.2220. Mediation of the Association between Prenatal Arsenic Exposure and Infant Birth Outcomes by DNA Methylation of DNMT3A**

Anne Bozack

*Anne Bozack<sup>1</sup>, Andres Cardenas<sup>2</sup>, Quazi Quamruzzaman<sup>3</sup>, Mahmuder Rahman<sup>3</sup>, Golam Mostofa<sup>3</sup>, David Christiani<sup>4</sup>, Molly Kile<sup>5</sup>*

**Abstract:** Background: Prenatal arsenic (As) exposure is negatively associated with birth weight and gestational age. Epigenetic changes, including DNA methylation (DNAm) play a critical role in fetal development. DNA methyltransferase 3 alpha (DNMT3A) is a key enzyme responsible for de novo DNAm and genomic imprinting. Thus DNMT3A is a prime candidate gene as a mediator between the prenatal environment and adverse birth outcomes. We evaluated the relationships between prenatal As exposure, gestational age (GA), birth weight (BW), and DNAm of DNMT3A. Methods: In a prospective Bangladeshi birth cohort, cord blood DNAm of three DNMT3A CpGs was measured using bisulfite pyrosequencing. Maternal toenail As concentration at birth was measured using inductively coupled plasma mass spectrometry to estimate fetal exposure. Among vaginal births (N=415), structural equation models (SEMs) were used to evaluate mediation by DNMT3A DNAm for the association between log<sub>2</sub>-maternal toenail As concentration, GA, and BW. Results: DNAm of the three CpGs was used to define a latent variable representing DNMT3A. In an unadjusted SEM, the effect of As concentration on BW was mediated by GA (indirect effect  $\beta=-0.02$  P=0.007). Arsenic concentration was positively associated with DNAm of DNMT3A (P=0.002). DNMT3A DNAm mediated the association between As concentration and GA ( $\beta=-0.05$ ; P=0.02), but not the association with BW. Overall, results adjusted for infant sex and maternal weight gain and education were consistent. DNAm mediated the association between As concentration and GA ( $\beta=-0.04$ ; P=0.02); mediation of the association between As concentration and BW by DNAm was borderline significant ( $\beta=-0.01$ ; P=0.06). In both unadjusted and adjusted models, the total effect of a doubling in As concentration was a decrease in GA of 2 days. Conclusions: DNMT3A plays a critical role in fetal epigenetic programming and may mediate the association between prenatal As exposure and birth outcomes.

## **P01.2230. Effect of In Utero Arsenic Exposure on Infant Birth Outcomes: Mediation by DNA Methylation of Cord Blood**

Anne Bozack

*5. School of Biological and Population Health Sciences, College of Public Health and Human Sciences, Oregon State University, Corvallis, OR, United States.*

**Abstract:** Background: In utero exposure to arsenic (As) is associated with adverse birth outcomes; this relationship may be mediated by epigenetic dysregulation. We evaluated the association between maternal prenatal As exposure, gestational age (GA), and birth weight (BW), and mediation by DNA methylation (DNAm). Methods: In a prospective birth cohort of pregnant women in Bangladesh exposed to As mainly through drinking water, maternal drinking water As was measured at  $\leq 16$  weeks GA, and toenail As was measured at  $< 1$  month postpartum. In a discovery phase, DNAm in cord blood was measured using the Infinium 450K array (N=44). In a validation sample of participants of the same cohort (N=570), cord blood DNAm was measured using bisulfite pyrosequencing for candidate CpG in miR124-3 (cg20277905), GNAL (cg06522054), and MCC (cg24937280) genes. Results: In the discovery phase, maternal water As was associated with DNAm of 396 CpGs ( $P < 1.10 \times 10^{-6}$ ;  $|\beta$  regression  $| > 0.10$ ). These CpGs were evaluated for associations with birth outcomes; 139 were associated with GA and one with BW ( $P < 0.05$ ). The main principal component of the top-ten CpGs fully mediated the inverse association between maternal prenatal water As and GA in a structural equation model (SEM) ( $P < 0.001$ ) but not for BW. In the validation phase, DNAm of miR124-3 and MCC mediated the association between maternal toenail As and GA (miR124-3  $P = 0.003$ ; MCC  $P = 0.006$ ). In an adjusted SEM including miR124-3 and MCC, the association between As and GA was mediated by DNAm of miR124-3 but not of MCC (miR124-3  $\beta = -0.04$ ;  $P = 0.02$  MCC  $P = 0.23$ ). Conclusions: miR124-3 is a microRNA coding gene that may be involved in embryonic growth, and in mouse models prenatal As exposure has been associated with miR124-3 expression. Using a discovery and validation approach, we show that DNAm of miR124-3 may mediate the association between prenatal As exposure and GA.

**P01.2240. Maternal Blood Cadmium Concentrations and Whole Blood DNA Methylation during Pregnancy in the Early Autism Risk Longitudinal Investigation (EARLI)**

Tun (Max) Aung

*Tun (Max) M. Aung<sup>1</sup>, Kelly Bakulski<sup>2</sup>, Jason Feinberg<sup>3</sup>, John Dou<sup>2</sup>, John Meeker<sup>1</sup>, Lisa Croen<sup>4</sup>, Irva Hertz-Picciotto<sup>5</sup>, Craig Newschaffer<sup>6</sup>, Daniele Fallin<sup>7</sup>*

- 7. Mental Health, Johns Hopkins University, Baltimore, MD, United States.*

**Abstract:** Background: During pregnancy, the maternal epigenome may be responsive to environmental exposures. We tested whether maternal exposure to cadmium (Cd) results in differential maternal whole blood DNA methylation (DNAm) in early pregnancy. Methods: Maternal blood samples were collected at the initial study visit (during trimesters one or two of pregnancy) from 232 participants in the Early Autism Risk Longitudinal Investigation (EARLI) pregnancy cohort. We measured maternal blood Cd (n=215) using inductively coupled plasma mass spectrometry, which reflects recent exposure (blood t<sub>1/2</sub> ~75 days), and measured maternal blood DNAm (n=201) on the Illumina 450K array; 93 non-smoking women had both measures available for analysis. Linear regression was used to test for site-specific associations between blood Cd and DNAm, adjusting for cell type composition and confounding variables. Results: The distribution of blood Cd was right skewed and log-transformed for statistical analyses. The geometric mean of blood Cd was 0.2 µg/L (Interquartile range = 0.13 µg/L). An interquartile range difference in blood Cd was associated with a 13.1% increase in B-cell proportions (95% CI: 1.0 - 25.2). In multivariable regression, six CpG sites were associated (p-value<10<sup>-5</sup>) with log blood Cd concentrations. At five of these sites, increasing blood Cd was associated with hypermethylation, and three corresponded to the genes LYN, TESC, and ESD. The CpG site near LYN was closest to genome-wide significance (p-value = 1.9x10<sup>-6</sup>), and an interquartile range difference in blood Cd was associated with an 8.4% increase in percent methylation at this site (95% CI: 5.1 - 11.6). Conclusion: We report site-specific associations between DNAm and blood Cd in early pregnancy. Future work will consider the persistence of DNAm marks. Identified sites may be potential biomarkers of Cd exposure that can inform future epidemiological studies or implicate downstream gene pathways affected by Cd exposure.

**P01.2250. Breastfeeding as a Predictor of Serum Concentrations of Per- and Polyfluorinated Alkyl Substances in Reproductive-Aged Women and Young Children: A Rapid Systematic Review**

Brianna VanNoy

*Brianna N. VanNoy<sup>1</sup>, Juleen Lam<sup>2</sup>, Ami R. Zota<sup>1</sup>*

*1. Department of Environmental and Occupational Health, George Washington University, Washington, DC, United States.*

*2. Program on Reproductive Health and the Environment, University of California, San Francisco, San Francisco, CA, United States.*

**Abstract:** Background: Per- and polyfluorinated alkyl substances (PFASs) are ubiquitous, synthetic chemicals widely detected in human serum and breast milk. Objective: We conducted a rapid systematic review to assess the association between breastfeeding practices and serum concentrations of PFASs among reproductive-aged women and young children. Methods: We searched PubMed and Scopus for human studies that measured breastfeeding behavior and evaluated their associations with serum PFASs concentrations in women and children. We evaluated each study for the risk of bias (internal validity), and assessed the overall quality and strength of the evidence following the Navigation Guide systematic review approach. Results: We identified 14 relevant studies. Longer breastfeeding duration was significantly associated with increased serum concentrations of PFASs among infants/toddlers. Previous breastfeeding duration was significantly associated with lower serum concentrations of PFASs in pregnant and/or postnatal women. Specifically, children had 1-3% lower serum perfluorooctanoic acid (PFOA) concentrations and women had 4.7-6.0% higher serum PFOA concentrations, per month of breastfeeding. The overall risk of bias was rated as "probably low risk," and the body of evidence was rated as "high" and "moderate" quality for studies that assessed women and children, respectively. Conclusion: We conclude there is "sufficient" evidence supporting an association between breastfeeding and serum PFASs concentrations among women, but "limited" evidence of an association among children due to limited sample size and potential bias from confounding and exposure misclassification. These findings reinforce that lactation is an important excretion route of PFASs for women, and that breast milk may be an important exposure pathway for young children. Future studies should further investigate the implications of our findings for maternal and child health.

**P01.2260. Associations of Serum Perfluoroalkyl Substance and Vitamin D Biomarker Concentrations in the National Health and Nutrition Examination Survey (NHANES), 2003-2010**

Abstract: Perfluoroalkyl substances (PFAS) are persistent endocrine disrupting chemicals found in industrial and commercial products. Previous research has shown that other endocrine disrupting chemicals such as phthalates and bisphenol A may alter circulating levels of vitamin D; however, no research has examined associations between PFAS and vitamin D biomarkers. We conducted a cross-sectional analysis of 7,040 individuals aged 12 years and older participating in the 2003-2010 cycles of the United States National Health and Nutrition Examination Survey (NHANES). Concentrations of four PFAS and total 25-hydroxyvitamin D [25(OH)D] were measured in serum samples. We used multivariable linear regression to estimate covariate-adjusted differences in total 25(OH)D per log 10-unit increase in PFAS concentrations. We assessed potential effect measure modification by gender, age, and race/ethnicity in stratified models. PFAS were detected in over 98% of the samples. After adjusting for confounders, a 10-fold increase in perfluorohexane sulfonic acid was associated with a 2.6 nmol/L increase (95% CI: 1.0, 4.2) in total 25(OH)D. Age, gender, and race/ethnicity did not modify this association. A 10-fold increase in perfluorooctane sulfonic acid was associated with a 2.8 nmol/L decrease (95% CI: 0.6, 4.9) in total 25(OH)D, with associations significantly stronger among whites ( $\beta$ : -5.3; 95% CI: -8.4, -2.3) and individuals older than 60 years of age ( $\beta$ : -5.8; 95% CI: -9.7, -1.8). Other PFAS were not associated with total 25(OH)D. Our results suggest that some perfluoroalkyl substances may be associated with altered vitamin D levels in the United States population, and associations may vary by chemical, age, and race/ethnicity.

**P01.2270. Association of Prenatal Exposure to Benzophenone-3 with Cognitive Function in 4.5-Month-Old Infants**

Abstract: Benzophenone-3 (BP-3) is typically found in sunscreen and cosmetic products to protect skin from sun damage. However, its effects on human health, including neurodevelopment, are largely unknown. We assessed the association between prenatal BP-3 exposure and performance on a physical reasoning task in 105, 4.5-month-old infants from an ongoing prospective pregnancy study in Illinois of mostly white (88%) women with 84% having at least a college education and 77% having a household income above \$50,000. Five first morning urines collected across pregnancy were pooled and we quantitated BP-3 in the pooled sample to estimate average BP-3 concentration in pregnancy. Concentrations of BP-3 in maternal urine were substantially higher (median [IQR]=123[324]) than concentrations reported in the National Health and Nutrition Examination Survey (median [95% CI] = 20[16-25]). Infants' looking time to two events - one physically impossible and the other possible - was recorded via infrared eye tracking. Infants who understand an event is impossible typically look longer at it than a possible event, with infant girls generally doing better than boys. Multivariable generalized linear models were used to examine the association of urine BP-3 with the difference in looking time between the two events (impossible - possible) adjusted for urine specific gravity, child sex, age, breastfeeding, household income, maternal education, and order of event presentation. Each interquartile range (IQR) increase in BP-3 was associated with a 622 msec decrease (95% CI: -40, -1204) in looking time difference score. Infant sex or event order did not significantly modify BP-3 associations. Findings suggest that higher prenatal BP-3 urine concentrations are associated with poorer physical reasoning at 4.5 months of age in both boys and girls, despite sexual dimorphism of the task. This result needs corroboration in a large sample. ES007326, ES022848, RD83543401, OD023272.

## **P01.2280. Serum-Adipokine Hormones from Birth to Puberty in Children Exposed to Perfluoroalkyl Substances**

Colleen Shelly

*Colleen E. Shelly<sup>1</sup>, Philippe Grandjean<sup>1</sup>, Youssef Oulhote<sup>1</sup>, Ruth Frikke-Schmidt<sup>2</sup>, Denis Zmirou<sup>3</sup>, Pal Weihe<sup>4</sup>, Dania Valvi<sup>1</sup>*

*4. Department of Occupational Medicine and Public Health, Faroese Hospital System, Tórshavn, Faroe Islands.*

**Abstract:** Background: Early life exposure to perfluoroalkyl substances (PFASs) has been associated with low birth weight and deviations in growth outcomes in children. Animal studies suggest these associations are mediated by PFAS interference with adipokine hormone regulation, but human data are limited. Aim: To evaluate the associations of early life PFAS exposures with adipokine hormone levels at birth and postnatally. Methods: We examined 80 mother-child pairs from a Faroese cohort born in 1997-2000. We measured 5 major PFASs in late pregnancy maternal serum and child serum at ages 5, 7 and 13 years. We used multivariable-adjusted regression models to assess the cross-sectional/prospective associations of PFASs (log<sub>2</sub>) with concentrations of 3 adipokines (ln-transformed, ng/mL) in cord blood and child serum at later ages. Results: Low to high correlations were seen for PFAS pairs within ( $0.09 \geq r \leq 0.83$ ) and between ( $0.15 \geq r \leq 0.74$ ) ages. Leptin showed mainly inverse associations that were significant for the cord blood concentrations with maternal serum PFOA ( $\beta$ [95%CI] per exposure doubling = -0.91[-1.71,-0.11]), leptin at ages 5 and 13 and maternal PFHxS, and for leptin at all postnatal ages and child serum-PFOS at previous/outcome ages. Cord blood adiponectin was associated with maternal serum concentrations of all PFASs, except PFOA (e.g.  $\beta$ [95%CI] per PFHxS doubling = -0.32[-0.63,-0.01]), while associations for postnatal adiponectin and child serum-PFASs were of smaller magnitude. Lower cord blood resistin was associated with maternal PFDA, and lower resistin at ages 5-13 was associated with child serum PFOS, PFOA and PFNA at previous/outcome ages. We found patterns of stronger inverse associations with leptin and adiponectin in girls, but stronger inverse associations with cord blood resistin in boys ( $p$ -sex interactions < 0.10). Conclusion: This study suggests potentially sex-specific associations of PFAS exposures with adipokine hormone levels at birth and throughout childhood.

## **P01.2290. Impact of In Utero and Adolescent Phthalate Exposure on Sexual Maturation Progression**

Abstract: Phthalates are endocrine disrupting compounds commonly found in consumer products, exposure to which may influence reproductive maturation in adolescence. Differential effects from exposure in utero versus later in life are understudied. We examined sex-stratified longitudinal associations between the geometric mean of 3 trimester-specific spot urine phthalate measurements and sexual maturation at two points in adolescence (8-14, 9-18 years), as well as cross-sectional associations at 9-18 years. Sexual maturation was assessed using Tanner stages and menarche onset for girls (N=246) and Tanner stages and testicular volume for boys (N=226). Generalized estimating equations for correlated ordinal multinomial responses were used to model relationships between phthalates and odds of transitioning to the next Tanner stage, while generalized additive (GA) mixed models were used to assess the odds of menarche. Cross-sectional analyses employed GA models (female N=281; male N=264). Among girls, MEP in utero exposure was associated with increased odds of being at a higher Tanner stage for breast development at 8-14 years, but with slower progression of breast development over the follow-up period (OR=0.74 per year; 95% CI: 0.57, 0.96) after adjustment for child age, BMI z-score and time between study visits. Similar results were found for breast development with in utero exposure to MEOHP, MBzP, and MCP. There were no significant associations of in utero exposures with pubertal stage among boys, but concurrent MEP exposure was associated with lower odds of progression of genital development (OR=0.87; 95% CI: 0.76, 0.99). These results suggest in utero exposure to phthalates may disrupt estrogenic pathways to impact breast development during puberty, and that exposure results in earlier onset but slower progression of sexual development. In addition, MEP exposure during late adolescence may impede genital development among boys.

## **P01.2300. Perfluoroalkyl Substances and Birth Outcomes: A Pool Analysis in the Danish National Birth Cohort**

Zeyan Liew

*Qi Meng<sup>1</sup>, Beate Ritz<sup>1</sup>, Jørn Olsen<sup>2</sup>, Zeyan Liew<sup>1</sup>*

*1. Epidemiology, University of California, Los Angeles, Los Angeles, CA, United States.*

*2. Public Health, Aarhus University, Aarhus, Denmark.*

**Abstract:** **BACKGROUND:** Perfluoroalkyl substances (PFASs) are widespread persistent organic pollutants. Animal studies indicated that in-utero PFAS exposure may affect fetal growth, but human studies findings are inconclusive. Few human studies evaluated adverse birth outcomes primarily due to small sample size. **METHODS:** We conducted a pooled analysis using data of 3,535 mothers and infant pairs from three sub-samples originating from the Danish National Birth Cohort (DNBC), with 1398, 545, and 1592 mutually exclusive births respectively. All sub-samples have first trimester maternal plasma concentrations of PFOS and PFOA, and 4 additional PFAS (PFHxS, PFNA, PFHpS and PFDA) were available in sub-sample 2 and 3. PFAS measures were analyzed as continuous variables after natural-log (LN) transformation or categorized into tertiles. We estimated changes in birth weight (grams) or gestational age (days), odds ratios (OR) and 95% confidence intervals (CI) for infants born preterm (< 37 gestational week) or low birth weight (< 2500 gram). Potential confounders were included, and sampling weights of each sub-sample were accounted in statistical analyses. **RESULTS:** We estimated that each LN-ng/ml increase in PFOS, PFOA and PFHpS was associated with a 64g, 51g or 55g decrease in average birth weight. Several PFASs (PFOS, PFNA, and PFHpS) were also associated with a small decrease in gestational age at delivery. Moreover, we estimated elevated ORs for PFOS and PFHpS and low birth weight and preterm. For instance, OR for low birth weight and preterm were 1.7 (95% CI 0.9, 3.2) and 2.0 (95% CI 1.2, 3.2) respectively comparing the highest to the lowest exposure tertile. **CONCLUSION:** Our pooled analyses demonstrated that several prenatal PFASs are inversely associated with birth weight and gestational age, and prenatal PFOS and PFHpS exposure may affect the risks of being born low birth weight and preterm. Our findings strengthen the evidence that in-utero PFAS exposures may affect fetal growth.

## **P01.2310. Multi-Sources Exposure to Pesticides during Pregnancy and Risk of Hypospadias and Cryptorchidism: The French National Birth Cohort Elfe**

Noriane Souleymane-Cognez

*Noriane Souleymane-Cognez<sup>1</sup>, Charline Warembourg<sup>2</sup>, Cécile Zaros<sup>3</sup>, Marie-Astrid Metten<sup>4</sup>, Ronan Garlantezec<sup>4</sup>, Marie-Aline Charles<sup>3</sup>, Rémi Béranger<sup>4</sup>, Cécile Chevrier<sup>1</sup>*

**Abstract:** Prenatal occupational exposure to pesticides has been associated to male reproductive tract abnormalities. Exposure of the general population might occur through other sources (domestic uses, diet and living proximity to crops) but little is known on the developmental effects of non-occupational exposure. We aimed to assess the association between this multi-sources exposure to pesticides during pregnancy and the risk of hypospadias and cryptorchidism. Among the 9,059 boys of the French birth cohort Elfe, 51 were diagnosed with hypospadias and 134 with cryptorchidism. Exposure was assessed from 1) self-reported domestic uses of 8 pesticide product types, 2) acreage within a 1000m-buffer around home for 11 crops using French spatialized data of soil occupancy and agricultural register, and 3) maternal daily intakes estimated from food-frequency questionnaire and national survey data for 60 pesticide residues in food. For each exposure source, due to high number of variables, best-predictors selection procedure (Elastic Net) was firstly used. We then used logistic regression to assess simultaneously associations for the multiple selected exposure sources, accounting for confounding. Multiple imputation was used to handle for missing data. An increased risk of hypospadias was observed in association with domestic uses against fleas and ticks (OR=1.58, 95% CI: 1.10;2.23), with acreage of barley within the 1000m-buffer around home (1.69, 1.17;1.44), and with dietary intakes of  $\lambda$ -cyhalothrin (2.09, 1.11;3.95). For cryptorchidism, an increased risk was associated with the acreage of miscellaneous cereal crops within the 1000m-buffer (1.59, 1.04;2.41). No association was observed with domestic uses nor with dietary exposure. Using population-based cohort, our results suggest a possible increased risk of hypospadias and cryptorchidism in association with prenatal exposure to pesticides from some dietary and residential sources. This work is limited by a modest number of cases.

**P01.2330. Gestational Perfluoroalkyl Concentrations and Thyroid Hormone Levels in Faroese Pregnant Women and Neonates: A Prospective Cohort Study**

Christina Xiao

*Christina Xiao<sup>1</sup>, Philippe Grandjean<sup>1</sup>, Dania Valvi<sup>1</sup>, Flemming Nielsen<sup>2</sup>, Pal Weihe<sup>3</sup>, Youssef Oulhote<sup>1</sup>*

*2. University of Southern Denmark, Odense, Denmark.*

*3. The Faroese Hospital System, Tórshavn, Faroe Islands.*

**Abstract:** Background: Exposure to perfluoroalkyl substances (PFASs) may disrupt maternal and neonatal endocrine function. Adequate thyroid hormone (TH) levels during pregnancy are essential for fetal and early childhood development. Objective: To assess the relationship between gestational PFAS exposures and maternal and cord TH levels. Methods: Data was collected from a cohort of 182 mother-child pairs from 1994-1995 in the Faroe Islands. The concentrations of 17 PFASs, including perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) were measured in maternal serum. Maternal and cord serum were measured for THs such as thyroid stimulating hormone (TSH), free thyroxine (FT4), thyroxine (T4), free triiodothyronine (FT3), free triiodothyronine resin uptake (T3RU), and free T4 index (FTI). We examined relationships between PFAS concentrations and TH levels using multivariable regression models and effect measure modification in sex-stratified analyses. Results: PFAS concentrations were mostly positively associated with both maternal and fetal TSH. PFOS and PFOA had the strongest estimates; doubling PFOS and PFOA concentrations were associated with 49% (95% CI: 18, 87%) and 33% (95% CI: 11, 59%) increase in cord TSH concentrations respectively. Perfluorooctanesulfonamide (PFOSA) was negatively associated with maternal FT4 and T3RU but positively associated with cord T4 and FTI levels. In mothers carrying female fetuses, doubling PFOS concentrations was associated with a 54% (95% CI: 14, 109%) increase in maternal TSH, but not in mothers bearing male neonates (-5%; 95% CI: -27, 24%). We did not observe consistent patterns for sex-stratified associations between gestational PFAS concentrations and cord TH levels. Conclusions: Prenatal exposure to several PFASs during pregnancy, such as PFOS and PFOA, is associated with increases in infant TSH levels. PFOS may also affect maternal TSH levels depending on the fetus's sex, the implications of which are still to be understood.

**P01.2340. Association between Serum Anti-Diphtheria Toxoid Antibodies and Drinking Water Arsenic Exposure in a Prospective Birth Cohort in Rural Bangladesh**

Barrett Welch

*Barrett Welch<sup>1</sup>, Sakila Afroz<sup>2</sup>, Golam Mostofa<sup>2</sup>, Omar Sharif<sup>2</sup>, Ranjit Halder<sup>2</sup>, Mahmuder Rahman<sup>2</sup>, Quazi Quamruzzaman<sup>2</sup>, Meghan Megowan<sup>1</sup>, Sharia M. - 3. Department of Environmental Health, Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

**Abstract:** Background. There is evidence that arsenic exposure in early life modulates humoral immunity. Objective. We examined the association between drinking water arsenic concentrations to diphtheria vaccine-antibody concentrations measured at age 5. Methods. A prospective cohort of pregnant women was recruited in Bangladesh (2008-2011). Drinking water arsenic was measured at  $\leq 16$  weeks gestation,  $< 1$  month birth, between ages 20 to 40 months, and between ages 4 to 5 years, in a total of 510 children. Serum was collected from children at age 5. Concentrations of anti-diphtheria toxoid IgG antibody were quantified using enzyme linked immunosorbent assays. Antibody concentrations below 0.1 IU/mL were considered insufficient for long-term clinical protection. Linear and logistic regression models assessed the association between vaccine antibody and arsenic concentrations. Results. We found negative associations between arsenic exposure and concentrations of vaccine antibodies. The largest effects occurred with exposures measured during the in utero and neonatal periods. A 1-unit increase in natural log maternal water arsenic at  $\leq 16$  weeks gestation was associated with 9.9% greater odds of insufficient clinical titers of anti-diphtheria antibody compared to being clinically protected (Odds Ratio(OR): 1.10, 95% confidence interval(CI): 1.00, 1.21). After adjusting for paternal income, maternal education, breastfeeding duration, birth type, sex, child age, and BMI at blood draw, this association was attenuated where a 1-unit increase in natural log maternal drinking water arsenic at  $\leq 16$  weeks gestation was associated with a 4.3% greater odds of insufficient clinical titers of diphtheria antibody compared to being clinically protected (OR: 1.04, CI: 0.93, 1.17). Conclusion. This study provides preliminary evidence early life arsenic exposure is associated with a decreased likelihood of clinically protective levels of serum antibody to diphtheria, despite appropriate immunization.

## **P01.2350. The Paraquat Exposures of Pregnant Women and Neonates in Agricultural Areas in Thailand**

Pajaree Konthonbut

*Pajaree Konthonbut<sup>1</sup>, Pornpimol Kongtip<sup>1</sup>, Noppanun Nankongnab<sup>1</sup>, Mathuros Tipayamongkhogul<sup>2</sup>, Witaya Yoosook<sup>3</sup>, Susan Woskie<sup>4</sup>*

- 4. Department of Public Health, University of Massachusetts Lowell, Lowell, MA, United States.*

Abstract: Although banned in over 50 countries, paraquat is a widely used herbicide in Thailand. Animal studies have found developmental impacts from fetal exposures, but there is no human data on potential fetal exposures among agricultural workers. This study recruited 79 pregnant women from three hospitals in agricultural areas in Thailand, and assessed paraquat concentrations in the urine of the women at 28 weeks of pregnancy, delivery and 2 months postpartum. Paraquat levels were also measured in the meconium of neonates. The subjects were interviewed about personal characteristics, agricultural activities and pesticide use patterns. The geometric mean (GSD) urinary paraquat concentrations at 28 weeks of pregnancy, delivery and 2 months postpartum were 2.04 (4.22), 2.06 (5.04) and 2.42 (5.33) ng/ml, respectively. The geometric mean (GSD) paraquat concentration in meconium was 33.31 (4.59) ng/g. There were no significant differences in urinary paraquat concentrations at 28 weeks of pregnancy, delivery and 2 months postpartum or in meconium levels between those whose self-reported occupation was agriculturist compared to those in non-agricultural occupations. However there were significant differences in paraquat exposures for those who reported agriculture related activities including: working outside, living near farmland where pesticides are sprayed, having a family member who is an agriculturist, drinking well water, or use of herbicides or use of paraquat by the pregnant woman or a family member.

**P01.2360. Parental Occupational Exposure to Potential Endocrine Disrupting Chemicals, Adverse Birth Outcomes, and Effects of Multi-Vitamin Supplements**

Huanhuan Zhang

*Huanhuan Zhang<sup>1</sup>, Meng Ren<sup>1</sup>, Luke Knibbs<sup>2</sup>, Qiong Wang<sup>1</sup>, Cunrui Huang<sup>1</sup>*

*2. School of Public Health, The University of Queensland, Herston, Australia, Herston, QLD, Australia.*

**Abstract:** Objectives: To assess the combined effects of maternal and paternal occupational exposure to EDCs on adverse birth outcomes, and further explore if folic acid and multi-vitamin supplements modified the effects. Methods: In a prospective study from Dec 2011 to Dec 2014 in Guangzhou, China, a total of 5734 parent-child pairs were included. Questionnaire designed according to job exposure matrix (JEM) was applied to collect parental occupational EDCs exposure history. We performed logistic regression to estimate the associations between parental EDCs exposure and adverse birth outcomes including preterm birth (PTB), term low birth weight (LBW), birth defects and congenital heart disease (CHD), and further explored whether the associations differed by maternal folic acid and multi-vitamin supplement during pregnancy. Results: Maternal exposure to EDCs was associated with increased risk of birth defects (aOR=1.55, 95% confidence interval (CI): 1.05-2.38), exposure for more than 1.5 years and direct exposure increased this association, the aOR and 95% CI were 2.72 (1.53-4.86) and 2.12 (1.27-3.56), respectively, the effect was stronger among those without using multi-vitamin during pregnancy (aOR=2.35, 95%CI: 1.16-4.72) (Interaction P<0.05). Maternal EDCs exposure for more than 1.5 years and direct exposure increased risk of CHD, the aOR and 95% CI were 2.85 (1.43-5.66) and 2.35 (1.31-4.22), respectively, the risk was also higher among those without multi-vitamin supplements (aOR=2.57, 95%CI: 1.13-5.82) (Interaction P<0.05). Paternal occupational EDCs exposure was associated with increased risk of term LBW (aOR=1.89, 95%CI: 1.02-2.39); this risk was higher among mothers who not using multi-vitamin supplements (aOR=1.35(95%CI:1.01-1.79) (Interaction P=0.03). Conclusion: Maternal EDCs exposure is associated with birth defects and CHD while paternal exposure is associated with term LBW. These associations were slightly higher among mothers without multi-vitamin supplements.

## **P01.2370. Prenatal RFR Exposure and Cognitive Development of 5-Year-Old Children**

Heesun Yang

*2. Department of Preventive Medicine, College of Medicine, Dankook University, Chungcheongnamdo, Cheonan, Korea (the Republic of).*

**Abstract:** Background There is a growing global concern about the potential harmful effects on human health as the use of cell phones and electronics increases dramatically. However, the health effects of children exposed to prenatal RFR (radiofrequency radiation) during pregnancy are not well known. The purpose of this study is to investigate the association between RFR exposure in the fetal period and cognitive development in 5-year-old children. Methods The subjects were 633 children aged 5-year-olds in the (MOCEH) cohort study. Of the 633 participants, 118 participated in the RFR exposure measurement using the personal exposure measuring device (EME-Spy100®, Satimo, France) before the birth of the child during the period 2007. 11. - 2010. 8. IQ for 5-year-olds was assessed using the Korean version of the Korean Intelligence-Revised Edition (K-WIPPSI-R). We estimated associations with a generalized linear model that adjusted for potential confounders. Gender, region, maternal education level, maternal occupation, maternal smoking and drinking, maternal IQ, average daily call time for children, cord blood lead were considered considered as confounding factors. Results The child's IQ was significantly higher for large urban residents than for industrial complexes, and most mothers (92.4%) used their mobile phones during pregnancy. The change in the child's total IQ with increasing non-phone RF index was -1.8, but not statistically significant (95%CI : -4.66, 1.08). Child's IQ tended to decrease with increasing RF indices, but not statistically significant. Conclusions We have not found evidence for a significant association between fetal RFR exposure and cognitive development in 5-year-old children. Acknowledgement This study was supported by the National Institute of Environmental Research and the IT R&D program of MSIP/IITP [2017-0-00961, Study on the EMF Exposure Control in Smart Society].

## **P01.2380. Dietary Exposure to Pesticides in Tannia in Pregnant Surinamese Women**

Firoz Abdoel Wahid

*Firoz Abdoel Wahid<sup>1</sup>, Ashna Hindori-Mohangoo<sup>2</sup>, Jeffrey Wickliffe<sup>1</sup>, Mark Wilson<sup>1</sup>, Cornelis Zijlmans<sup>3</sup>, Maureen Y. Lichtveld<sup>1</sup>*

- 3. Research Center Academic Hospital Paramaribo, Paramaribo, Suriname.*

**Abstract:** Background Suriname's (8.8 kg active ingredient/ha) neurotoxic pesticides use is among the highest Caribbean-wide. The Caribbean Consortium for Research in Environmental and Occupational Health is assessing exposure to selected pesticides in 1000 vulnerable mother/child dyads. Environmental assessments showed residues of prohibited endosulfan and lindane in tannia (*Xanthosoma brasiliense*). This study assessed dietary exposure to these pesticides in tannia. Methods An interviewer-assisted survey in 696 participants assessed body weight (BW) and consumption and intake rates (IRs) of produce. A preliminary deterministic non-cancer risk assessment and a sensitivity analysis were conducted using USEPA's reference doses (RfDs) for endosulfan and lindane. Tannia consumption-associated risk was determined using the hazard quotient (HQ). Results Tannia was the most frequently consumed leafy vegetable (89%); mean IR 0.028 kg/day (range: 0.001-0.531 kg/day). Mean BW: 72 kg (range: 34-138 kg). Average case scenario: Tannia critical IRs > actual IRs (7.8 kg/day for endosulfan, 0.9 kg/day for lindane), HQ < 1 and the levels of concern (LoCs) were 221x > for endosulfan and 26x > for lindane compared to detected pesticide residue levels. Worst case scenario (lowest BW, highest IR and highest pesticide residue level) for lindane: Tannia critical IR (0.3 kg/day) ~ actual IR; HQ > 1; LoC < highest detected pesticide residue level. Discussion Dietary exposure to endosulfan in tannia does not seem to pose a risk for adverse health effects, but exposure to lindane in tannia in the worst-case scenario potentially does. Since the current RfDs for endosulfan and lindane are based on non-neurotoxic endpoints, the risk assessment findings must be interpreted cautiously. Funding FIC/NIH R24TW009570, R24TW009561, U01TW010087-01, U2RTW010104

**P01.2390. Autism Spectrum Disorders in Catalonia, Spain: A New Population-Based Case-Cohort Study to Investigate Environmental Factors**

Monica Guxens

*Laura Pérez-Crespo<sup>1</sup>, Monica Guxens<sup>1</sup>*

*1. ISGlobal, Barcelona, Spain.*

**Abstract:** Background: Autism spectrum disorders (ASD) are neurodevelopmental disorders characterized by impaired social interaction, deficits in social communication and restricted, repetitive, and stereotyped behaviors. Studies conducted in Northern Europe and United States have estimated an ASD prevalence of 0.61% and 0.67% respectively. In Spain there is only one small epidemiological study conducted in the Canary Islands in 2012 that shown a prevalence of 0.61%. The aim of this study is to estimate the ASD prevalence in 2016 and the cumulative yearly incidence between 2010 and 2016 in children in Catalonia, Spain. Methods: We set up a population-based cohort that included all children between 0 and 18 years of age insured in the Catalan Health System between 2010 and 2016. We identified all ASD cases diagnosed between 2010 and 2016 from the registry of the Catalan Health System (named Minimum Basic Data Set) by the ICD-9 codes 299.0, 299.1, 299.8, and 299.9. We estimated the ASD prevalence for 2016 and the cumulative yearly incidence between 2010 and 2016 with the 95% confidence intervals based on Poisson error structure. Results: We estimated an ASD prevalence of 0.93% (95% CI 0.88, 0.98) in children from 0 to 18 years of age in Catalonia in 2016. The ASD prevalence was 0.76% (95% CI 0.67, 0.84) in boys and 0.17% (95% CI 0.10, 0.24) in girls, with a sex ratio 4.44-fold higher in boys than girls. The ASD incidence increased from 0.06% (95% CI 0.01, 0.10) in 2010 to 0.18% (95% CI 0.10, 0.26) in 2016. Conclusions: The estimated ASD prevalence of 0.93% was higher than the average estimate reported in previous studies in Europe or United States. The prevalence was higher in boys than girls, with a sex ratio similar to previous studies. We also observed an increasing temporal trend of the ASD incidence in recent years. This new case-cohort study on ASD will allow investigating the role of environmental factors in the origins of ASD.

## **P01.2400. Urinary Phthalate Metabolites in Relation to Children's Asthmatic and Allergic Symptoms in Shanghai**

Wenming Shi

*Wenming Shi<sup>1</sup>, Chenxi Liao<sup>2</sup>, Jialing Zhang<sup>2</sup>, Wei Liu<sup>2</sup>, Heng Wang<sup>3</sup>, Chen Huang<sup>2</sup>, Haidong Kan<sup>1</sup>, Zhuohui Zhao<sup>1</sup>*

**Abstract:** **BACKGROUND:** Few studies can be found on phthalates exposure in relation to childhood asthma and allergic symptoms from mainland of China, where a persistent increase of childhood asthma and allergic disease has been observed. **OBJECTIVES:** We aimed to find out the exposure levels of phthalates and its relationship with children's asthmatic and allergic symptoms in Shanghai. **METHODS:** A follow-up study(2013-2014) in 434 children 5-10 years of age was completed, based on the China, Children, Homes, Health(CCHH) study(2011-2012). Asthmatic and allergic symptoms (wheeze, rhinitis, eczema) were collected by questionnaire and 10 phthalate metabolites were analyzed in morning urine samples. Multiple logistic regression was applied to estimate the associations between symptoms and phthalate metabolites controlling for demographics, family history of allergic diseases and other covariates. **RESULTS:** Nine out of 10 phthalate metabolites were detected in all subjects (average detection rate 93.2%). By multiple regression analyses, the 4th quartile of MnBP(reference: The 1st quartile) had the adjusted odds ratios(AOR) and 95% confidence interval(95%CI) by 2.48(1.15-5.37), 2.18(1.05-4.54) and 3.09(1.22-7.83) for wheezing, rhinitis and eczema, respectively, while MiBP for rhinitis and eczema by 2.31(1.12-4.73) and 2.95(1.05-8.51), respectively. MEHHP and MEOHP were significantly associated with eczema by 3.14(1.12-8.83) and 2.65(1.02-6.85), respectively. By summing up the 4 low molecular weight(MW) metabolites and all 9 metabolites, the 4th quartiles of the sums were significantly associated with all symptoms. Subjects with 2 or 3 concomitant symptoms(reference: no symptoms) had significant positive associations with most of the above phthalate metabolites. **CONCLUSIONS:** Low MW metabolites such as DnBP and DiBP, high MW of DEHP and the total amount of phthalate metabolites might have adverse health effects on asthma and allergic symptoms in Chinese children.

## **P01.2401. Associations of Maternal Pregnancy Urine Estrogen Levels with Phthalate and Phthalate Replacement (1,2-Cyclohexane Dicarboxylic Acid Diisononyl Ester, DiNCH) Metabolites**

**Abstract:** Rationale: Pregnant women are exposed to phthalates in food, personal care and household products. Phthalates alter estrogen levels in experimental models but their potential to impact levels in human pregnancy is not well characterized. Methods: 291 participants in an Illinois pregnancy cohort collected 5 urines across pregnancy for pooling and quantification of 16 phthalate/DiNCH metabolites. Exposures were expressed as the molar sum of metabolites for:  $\sum$ DiNCH,  $\sum$ DEHP,  $\sum$ DBP,  $\sum$ DiBP,  $\sum$ DiNP,  $\sum$ PCP, and  $\sum$ AA (respective personal care product and anti-androgenic phthalates). At 10-14, 28-30 and 34-36 gestational weeks (GW), urine estradiol, estrone, estriol and metabolites were measured and summed ( $\sum$ E). Specific gravity adjusted exposure and  $\sum$ E data were log-transformed. Linear mixed-effects models assessed relationships of phthalates/ $\sum$ DiNCH with  $\sum$ E controlling for fetal sex, maternal age, pre-pregnancy BMI,  $\sum$ E analytic batch, and GA at urine collection for  $\sum$ E evaluation. Interactions of phthalates/ $\sum$ DiNCH, fetal sex,  $\sum$ E batch, and GA at  $\sum$ E urine collection were explored. Results: Participants were 82% white, 72% had income >\$60,000/yr, 84% had a college+ education, and urine biomarker levels were similar to U.S. women. At 10-14 weeks,  $\sum$ E increased with increasing:  $\sum$ DBP (b=1.5, 95% CI=0.5, 2.5),  $\sum$ DiNP (b=1.3, 95% CI=0.6, 2.0),  $\sum$ PCP (b=0.5, 95% CI=0.1, 0.8), and  $\sum$ AA (b=0.4, 95% CI=0.01, 0.7); associations in late pregnancy were attenuated and non-significant.  $\sum$ E increased with increasing  $\sum$ DEHP in women carrying females (b=0.7, 95% CI=0.2, 1.3) and  $\sum$ DiBP in women carrying males for  $\sum$ E measured in only one analytic batch.  $\sum$ E was not associated with  $\sum$ DiNCH. Conclusions:  $\sum$ DBP,  $\sum$ DiNP,  $\sum$ PCP, and  $\sum$ AA phthalates were associated with higher gestational  $\sum$ E in early but not later pregnancy. For other phthalates, associations were only in small sub-group analyses. Whether pregnancy estrogen levels mediate associations between phthalates and pregnancy outcomes merits investigation.

## **P01.2402. Associations of Prenatal Exposure to Triclosan and Benzophenone-3 with Visual Recognition Memory in 7.5-Month-Old Infants**

Kelsey Dzwilewski

Abstract: Triclosan (TCS) is used in personal care products as an antimicrobial agent and benzophenone-3 (BP3) is used in personal care products and plastics as an ultraviolet absorber. Due to their endocrine disrupting properties, prenatal exposure to these chemicals may affect brain development, but little is known about their effect on infant cognition. Prenatal exposure to TCS and BP3 and visual recognition memory (measured by novelty preference) were assessed in 177 7.5-month-old infants participating in a prospective study in Illinois, USA. Study mothers were mostly white (86%), with 88% having at least a college education and 75% a household income above \$60,000. In a pool of five first morning urine samples collected across pregnancy, we quantified (median[IQR]) TCS (14.1[63.1] µg/L) and BP3 (118.6[273.0] µg/L). Infrared eye tracking recorded infant looking time at a trial with two identical faces followed by trials in which the familiar face was paired with a novel face. General linear models were used to assess associations of each exposure biomarker (adjusted for urine specific gravity) with novelty preference (percent time looking at the novel face) adjusted for infant age, gestational age, birth weight, sex, assessment condition, household income, and maternal IQ and education. There were no associations of TCS or BP3 with novelty preference and no sex differences in associations. Each IQR increase in TCS was associated with a 0.10% decrease (95% CI: -0.49,0.29) in novelty preference, while each IQR increase in BP3 was associated with a 0.04% increase (95% CI: -0.38,0.47). Generalized additive models showed no evidence of nonlinear associations of either TCS or BP3 with novelty preference. This preliminary analysis found no evidence associating maternal prenatal urinary TCS or BP3 with infants' recognition memory at 7.5 months, but the results need to be confirmed in a larger sample. **Abstract:** Background: The gut microbiome is influenced by early-life exposures, but—despite potentially enormous implications for child health—it is understudied in environmental health. This pilot study, the first to explore the effect of in utero exposures on long-term development of the microbiome, examined the association between first trimester and perinatal exposure to PBDEs and PCBs and the mid-childhood gut microbiome. Methods: We measured metabolites of PBDE-47, -99, -100, and -153 and PCB-138, -153, and -180 in maternal plasma during the first trimester (n=18) and at delivery (n=25) using gas chromatography coupled with tandem mass spectrometry in women from Sherbrooke, Quebec who identified as white and ever breastfed the child subject. The structure of the mid-childhood (6-8 years) fecal microbiome was measured using 16S rRNA sequencing. Sequences were processed using QIIME and paired to operational taxonomic units (OTUs) using SILVA v128. To test for differences at the OTU level, we used the MiCAM algorithm, adjusting for delivery mode and socioeconomic status. Results: Higher first trimester PCB-153, -180, and  $\Sigma$ 3PCB blood concentrations were associated with a higher relative abundance of Propionibacteriales and Propionibacteriaceae in mid-childhood. Higher PCB-180 and  $\Sigma$ 3PCB were associated with higher relative abundance of Bacillales Family XI. Higher PBDE-99 exposure was associated with a decrease in uncultured bacteria within the Ruminococcaceae NK4A214 group and PBDE-47 was associated with differences in Ruminococcus 2, but the direction of the association varied by lower-level taxa. These OTU-level changes did not result in differences to within- or between-subject diversity. Exposures at delivery were not associated with differences in OTUs. Conclusion: Early-life exposure to PCBs and PBDEs was associated with differences in the mid-childhood gut microbiome. Larger studies are needed to confirm these results and explore health implications.

**P01.2404. Preterm Birth among Infants Exposed to In Utero Ultrafine Particle Emissions from Aircraft Engines near the Los Angeles International Airport**

Sam Wing

Abstract: Ambient air pollution is a known risk factor for adverse birth outcomes, but the role of ultrafine particles (UFPs) is not yet well understood. UFP emissions from aircraft are spread across large residential areas downwind of airports, possibly causing a considerable reproductive health burden. Birth certificate data from the California Department of Public Health was drawn from all births by mothers living in a 200 mi<sup>2</sup> area downwind of Los Angeles International Airport (LAX) in 2011 (n=16,268). These records were used to ascertain the presence preterm birth (PTB), as well as maternal covariate information. To assess in utero exposure to UFPs, we input geocoded maternal addresses into a novel geospatial UFP dispersion model that has been validated by extensive ground-level measurements near LAX. We used multiple logistic regression, regressing PTB (live birth < 37 weeks gestation) on UFP concentrations estimated from the dispersion model. We adjusted for maternal factors like age, educational attainment, and race/ethnicity. We further adjusted for measures of air pollution from other sources, like traffic, including PM<sub>2.5</sub>, nitrogen oxides, and surface ozone to isolate the role of aircraft-related UFPs. An interaction term between UFPs and maternal nativity was included in the model. Among this birth cohort, we found an 11% increase in odds (95% CI: 1.01, 1.22) of PTB per interquartile range of UFP exposure. When stratified by maternal nativity, no increase in PTB among infants of foreign-born mothers was detected (OR = 1.02, 95% CI: 0.90, 1.16) but was detected among infants of US-born women (OR = 1.19, 95% CI: 1.06, 1.32). Effect modification by nativity was borderline statistically significant (p = 0.04). We found increased exposure to aircraft-related UFPs was associated with an elevated risk of PTB, serving as evidence of the reproductive health effects of UFP exposures from aircraft emissions. However, this relationship appears to be modified by maternal nativity.

## **P01.2405. The Effect of Prenatal Bone Lead Concentrations on Prepulse Inhibition: A Prospective Study of Mexican Children**

**Abstract:** Background: An important concern is the toxic legacy of prenatal lead exposure. During pregnancy, maternal skeletal bone lead from earlier exposures mobilizes and crosses placental barriers placing the developing fetus at risk for lead exposure and subsequent neurobehavioral deficits. Some of the neuronal circuits implicated in mechanisms of neurodevelopment can be probed with simple physiological behavioral paradigms, potentially serving as a neurobehavioral marker of toxicant exposure. One such measure includes pre-pulse inhibition (PPI), a sensorimotor gating process that can modify the acoustic startle reflex (ASR) under different behavioral conditions. PPI impairment has been associated with neurodevelopmental deficits in children such as ADHD and early psychosis. To our knowledge, no studies have examined the effect of prenatal lead concentrations on PPI in children. Objective: The objective of this study was to determine the effect of prenatal bone lead concentrations on PPI in Mexican children 8-17 years of age. Methods: In vivo maternal bone lead measurements were taken at four weeks postpartum at the mid-tibia shaft and the patella using a K-Shell X-ray fluorescence (K-XRF) instrument. PPI responses were recorded in an isolated clinical setting and eye blink responses were assessed using electromyography. We used ordinary least squares regression adjusted for relevant covariates to model the relationship between prenatal bone lead and PPI. Results: Mean  $\pm$  SD lead concentrations in tibia and patella were  $9.33 \pm 10.00$   $\mu\text{g/g}$ , and  $12.27 \pm 12.17$  respectively. In adjusted models, higher tibia bone lead significantly reduced PPI in children. Patella lead concentrations were independent of PPI. Conclusions: In this population of Mexican children, prenatal tibia lead concentrations were associated with impaired PPI. These results suggest that lead may disrupt PPI, which could be a biological indicator of neurodevelopmental deficits in children.

## **P01.2406. Intrauterine Exposure to Polychlorinated Biphenyls (PCBs) and Anogenital Distance in Israeli Newborns**

Eva Siegel

*Eva Siegel<sup>1</sup>, Revital Sheinberg<sup>2</sup>, Rimona Keidar<sup>2</sup>, Elkana Kohn<sup>2</sup>, Amalia Levy<sup>3</sup>, Ronit Lubetsky<sup>4</sup>, Dror Mandel<sup>4</sup>, Pam Factor-Litvak<sup>1</sup>, Matitiahu Berkovitch<sup>2</sup>*

- 3. Ben Gurion University, Beersheva, Israel.*
- 4. Tel Aviv Medical Center, Tel Aviv, Israel.*

**Abstract:** Polychlorinated biphenyls (PCBs) are widespread environmental contaminants due to their extensive past use, long-range transport and persistence in adipose tissues of humans and animals. Specific congeners exhibit structural similarities to steroid hormones. This raises concerns regarding the effects of exposure on reproductive development in neonates. Here, we examine associations between prenatal exposure to PCB congeners 118, 138, 153 and 180 and anogenital distance in a cohort of newborns in Israel. We measured serum concentrations of the four PCB congeners in 173 pregnant women presenting to the delivery room at Assaf Harofeh Medical Center. Mothers completed questionnaires on lifestyle and demographic variables. Birthweight, length, head circumference and anogenital distances were measured using a standard protocol. Regression models estimated associations between maternal PCB exposure and infant anogenital measurements, birthweight, birth length and head circumference, controlling for confounding variables. Mean penile width, anoscrotal length, and anopenile length were 11.04 mm [standard deviation (sd): 1.14 mm], 23.43 mm (sd: 3.58), and 44.58 mm (sd: 4.58 mm) in male infants (n=90); mean anoforchetall and anoclitoral distances were 14.34 mm (sd: 2.17 mm) and 34.23 mm (2.74 mm) in female infants (n=83). Mean maternal serum concentrations were 2.91 ng/ml (sd: 1.93), 4.50 ng/ml (sd: 3.04), 7.42 ng/ml (sd: 5.41), and 4.98 ng/ml (sd: 3.62) for PCB-118, 138, 153 and 180, respectively. Higher maternal concentrations of all four PCBs were associated with reduced anogenital distance measures in male infants but not in female infants. No associations were found between PCB exposure and birthweight, length and head circumference. These results are significant as anogenital distance is associated with male reproductive problems later in life; thus, there are implications for later life reproductive health.

## P01. Adult Health Effects of Environmental Exposures 1

### **P01.2410. Association of Cumulative Exposure to Heavy Metal Mixtures with Obesity and Its Comorbidities among U.S. Adults in NHANES 2003-2014**

Xin Wang

*Xin Wang<sup>1</sup>, Ning Ding<sup>1</sup>, SungKyun Park<sup>1</sup>*

*1. Epidemiology, University of Michigan, Ann Arbor, MI, United States.*

**Abstract:** Background: Some heavy metals have been associated with obesity and obesity comorbidities. The associations have typically been examined for individual metals. Objectives: We update our Environmental Risk Score (ERS), a summary measure to examine the risk of exposure to multi-pollutants in epidemiologic research, to evaluate the associations of cumulative exposure to a mixture of correlated heavy metals with obesity and its comorbidities including hypertension (HTN), and type-2 diabetes mellitus (T2DM) while accounting for high degree correlations and potential interactions among metal mixtures components. Methods: We examined blood and urinary measurements of 18 heavy metals among 9,537 adults in NHANES 2003-2014. We randomly split data into a training set for the construction of ERS (n=6,675) and a testing set for validation (n=2,862). ERS of heavy metal mixtures were computed for obesity using adaptive elastic-net (AENET) with 189 predictors including 18 main effects, 18 square terms, and 153 pairwise interactions of heavy metals. Regression analyses with complex survey designs were performed to assess the association of ERS with obesity and its comorbidities. Results: 8 main effects (BPb, BCd, BHg, UDMA, UMMA, UBa, UHg and UTI), 3 square terms (BCd, UCd and USb), and 7 pairwise interactions (BPb&UCd, BPb&UMMA, BPb&UU, UCd&UMMA, UDMA&UW, UPb&USb and UMMA&UCo) of heavy metals have been selected by AENET for construction of ERS of obesity-related heavy metal mixtures. The ERS was positively associated with waist circumference, body mass index, skinfold thickness and total body fat, independent of age, sex, race/ethnicity, education, smoking, physical activity and NHANES cycle ( $P_s < 0.05$ ). Positive associations of ERS with both HTN and T2DM have also been observed ( $P_s < 0.05$ ). Conclusions: Our study suggests the potential role of exposure to heavy metals mixtures as a contributing factor to obesity and its related chronic conditions such as hypertension and T2DM.

**P01.2420. Assessing the Relation between Plasma PCB Concentrations and Elevated Autistic Behaviour Using Bayesian Predictive Odds Ratios**

Brendan Bernardo

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental condition characterized by impaired social communication and repetitive or stereotypic behaviours. In utero exposure to environmental chemicals, such as polychlorinated biphenyls (PCBs), may play a role in the etiology of ASD. We examined the relation between plasma PCB concentrations measured during pregnancy and autistic behaviours in children aged 3-4 years old in the Maternal-Infant Research on Environmental Chemicals (MIREC) Study, a pregnancy and birth cohort of 538 mother-infant pairs from Canada (enrolled: 2008-2011). We quantified the concentrations of 6 PCB congeners in plasma samples collected during the 1st trimester. At age 3-4 years, caregivers completed the Social Responsiveness Scale-2 (SRS), a valid and reliable measure of children's reciprocal social and repetitive behaviors and restricted interests. We examined SRS scores as both a continuous and binary outcome and calculated Bayesian predictive odds ratios for more autistic behaviour based on a latent variable model with a threshold SRS >60. We found very small and imprecise increases in the mean SRS score for the highest quartile of plasma PCB concentrations compared to the lowest quartile, but these were accompanied by larger increases in the odds of more autistic behaviour. For instance, an average increase of 0.7 [95%CI: -0.8, 2.3] in the mean SRS (Q4 versus Q1) for PCB138 translated to an odds ratio of 1.5 [95%CI: 0.9, 2.3]. In conclusion, we found some evidence that plasma PCB concentrations during pregnancy may be associated with small increases in autistic behaviours in this cohort. Our findings demonstrate the importance of measuring associations between PCBs and autistic behaviour on both continuous and binary scales.

## **P01.2430. Data Synthesize for Semantic Fine-Grained Prediction of Lung Nodule in CT Images**

Zhiqin Liu

*Qingfeng Wang<sup>1</sup>, Zhiqin Liu<sup>1</sup>, Jun Huang<sup>1</sup>*

*1. School of Computer Science and Technology, Southwest University of Science and Technology, Mianyang, Sichuan, China.*

**Abstract:** Background/Aim Semantic terms of lung nodules such as lobulation, spiculation, malignancy, etc. can be commonly found in radiology reports to describe the semantic characteristics for diagnostic reference. The prevalence of malignancy among pulmonary nodules ranges between 0.2% and 50%. The main purpose of fine-grained prediction is to differentiate subordinate categories of the same semantic base classes and to provide an imaging biomarker with richer quantitative assessments of nodules for better prevalence estimation and diagnostic decision. Challenges Since some subtypes or stages of one disease are rare but important, significant data imbalance might present and render the prediction problem very arduous. Data imbalance could bias the learning frameworks and is essential in the popularization of data-hungry deep learning paradigms. However, this problem was not elaborated in previous works of lung nodules. Methods We explored the cutting-edge Wasserstein Generative Adversarial Networks (WGAN) to address the data imbalance issue with over-sampling on the minority classes and tested this method on the public Lung Imaging Database Consortium (LIDC) dataset. The WGAN can estimate the underlying distribution of a minority class to synthesize more plausible and helpful samples for the prediction model. Results The experiment shows that the proposed method improves F-measure by an average of 9.53% for the smallest minority classes compared to conventional method. It suggests that the WGAN technique can synthesize helpful samples for minority classes to assist the training of the Convolutional Neural Network (CNN) model and to boost fine-grained prediction performance. Conclusion More synthesized samples obtained by considering the underlying distribution of minority classes will benefit the prediction. Future work will explore the relation among semantic terms for the data synthesis to simplify the oversampling process as well as to boost the synthetic quality even further.

## **P01.2450. Identifying Geospatial Patterns of Aggressive Breast Cancer Incidence Using North Carolina State as a Model**

Larisa Gearhart-Serna

**Abstract:** Breast cancer is a complex disease influenced by multiple factors, and overall survival improvements are hindered by aggressive and advanced cases that are not well understood. Our objective was to evaluate geographic variability in the prevalence of late stage metastatic breast cancer and total breast cancers in North Carolina. NC represents a state with geographic variability in cancer incidence, demographics, and environmental factors, making it an ideal location for this study. We collected breast cancer patient data from the North Carolina Central Cancer Registry for years 2009-2014, and derived summary staging was used to classify cases as in situ, localized, regional, or distant/metastatic. Total incidence data was averaged to reflect a 6-year incidence average. Age-adjusted standardized incidence ratios (SIRs) and 95% confidence intervals were then calculated for total breast cancer and distant/metastatic breast cancer for each county in NC. Prior studies have identified NC as part of a high breast cancer incidence region in the US, but there remains insufficient granular analysis such as the described methodology. We identified several counties in North Carolina with statistically significant high SIRs for breast cancer on the outer western and eastern regions of the state. For distant/metastatic breast cancers, statistically significant high SIRs were located primarily in the northeastern coastal region. We intend to investigate these counties further in correlation with environmental factors, including industry-derived, air, soil, and water contamination, and a variety of social, behavioral, and demographic factors. Overall our data identifies differential regions of NC with higher than expected incidence of total versus aggressive breast cancers, suggesting that different demographic or environmental factors may play a role in the observed variability. This work was supported by Duke Cancer Institute Cancer & Environment Funds and NIEHS T32-ES021432.

## **P01.2470. Possible Risks of High Altitude Exposure on Prostate Diseases**

Diana Alcantara-Zapata

*Diana E. Alcantara-Zapata<sup>1</sup>, Gustavo F. Gonzales<sup>2</sup>*

*1. Epidemiology - Public Health School, University of Chile, Santiago, Region Metropolitana, Chile.*

*2. Department of Biological and Physiological Sciences, Universidad Peruana Cayetano Heredia, San Martin de Porres, Lima, Peru.*

Abstract: More of 200 million people lives permanently over 2000 meter above sea level worldwide. In addition, a big proportion of the population in the world is exposed acute, intermittently and chronically to high altitude due to work, sports, tourism among others. From 5-20% of the population living at HA is diagnosed of EE (Hb>21 g/dl in men) and CMS. In Andean populations, this high production of erythrocytes has been associated with activation of gene SENP1, which in time is related to increased androgenic activity. Epidemiological study has demonstrated that OR for prostate cancer is increased at high altitude. A recent work from our laboratory showed that PSA levels were lower in men less than 40 years living at HA. Prostate cancer at sea level was associated to activation of the gene SENP1. According to these data is suggested that prostate cancer could be a risk for population with EE sharing elevated testosterone levels at HA. Interestingly, prostate disease at sea level and EE at HA share similar molecular and physiological mechanisms such increase of hypoxic induced factor (HIF), hematocrit (Hcto) and prostatic specific antigen (PSA). In addition, higher expression of the SUMO sentrin specific peptidase 1 (SENP1) is associated with higher androgen activity in Andean highlanders with excessive erythrocytosis (EE) and this expression promotes the development or progression of prostate cancer. Therefore, is important to perform a research to identify the existence of these factors in males with EE living at HA with the purpose of prevent and treat opportunely prostate diseases.

## **P01.2480. Indoor Tanning and the Risk of Developing Non-Cutaneous Cancers: A Systematic Review and Meta-Analysis**

Dylan O'Sullivan

*Dylan E. O'Sullivan<sup>1</sup>, Troy Hillier<sup>1</sup>, Darren R. Brenner<sup>2</sup>, Cheryl Peters<sup>3</sup>, Will King<sup>1</sup>*

*1. Public Health Sciences, Queen's University, Kingston, ON, Canada.*

*2. Oncology and Community Health Sciences, University of Calgary, Calgary, AB, Canada.*

*3. Cancer Epidemiology and Prevention Research, Alberta Health Services, Calgary, AB, Canada.*

**Abstract:** Background: While, the relationship between indoor tanning and skin cancer is well established, the risk of developing a non-cutaneous malignancy from indoor tanning use is unknown. Given that sun exposure may protect against certain non-cutaneous cancer sites, perhaps through increased vitamin D production, it has been argued that indoor tanning could also be protective. However, radiation from indoor tanning devices is 10 to 15 times stronger than midday sun and primarily emits UVA rays, which are relatively ineffective at stimulating vitamin D synthesis. Methods: We conducted a systematic review and meta-analysis of case-control and cohort studies that investigated the association between indoor tanning and a number of non-cutaneous cancer sites. Associations were estimated using random effects models. Heterogeneity was investigated through subgroup analyses and the Q-test and I<sup>2</sup> statistics. Results: 15 studies examining 12 cancer sites were included. Control for sun exposure was a significant source of heterogeneity in the association of indoor tanning and non-cutaneous cancer risk (meta-regression  $p = 0.0043$ ). When restricting to studies that controlled for sun exposure (7 studies and 19 effect estimates) no association was observed among ever users of indoor tanning devices with the risk of solid non-cutaneous cancers (pooled relative risk = 0.98; 95% CI: 0.94-1.03), while a suggestive increased risk was observed among hematologic malignancies (pooled relative risk = 1.11; 95% CI 0.96-1.28). Neither study design (prospective cohort vs. case-control) nor geographic region (North America vs. Europe) were significant sources of heterogeneity. Conclusion: This is the first meta-analysis examining the risk of non-cutaneous cancers from the use of indoor tanning devices. Given the well-established relationship with skin cancer and potential relationship with hematologic malignancies, efforts to reduce the use of indoor tanning devices should continue.

**P01.2490. Temporal and Spatial Excess Leukemia Deaths Around the Nuclear Power Plant in Kyushu, Japan (1970-2005)**

Yumiko Miyano

Yumiko Miyano<sup>1</sup>, Toshihide Tsuda<sup>2</sup>, Eiji Yamamoto<sup>3</sup>

1. Graduate school of Medicine, Dentistry, and Pharmaceutical Sciences, Okayama university, Okayama-city, Japan.

2. Graduate School of Environmental and Life Science, Okayama University, Okayama, Japan.

3. Okayama University of Science, Okayama, Japan.

**Abstract:** Background/Aim Excess incidence of cancer including leukemia among people living in the vicinity of Nuclear Power Plant (NPP) in normal operation has been reported on from Germany, France, the United Kingdom, Korea, and others. But in Japan, any epidemiologic investigations have not been conducted yet while 18 NPP facilities have discharged radioactive substances e.g. tritium. 13 among 47 prefectures in Japan had NPPs until 2010, and 7 of them were ranked in top 15 leukemia mortality. We estimated the Standardized Mortality Ratios (SMRs) on leukemia of municipalities around the NPPs in Kyushu area, the western parts of Japan, and then summarized their temporal-spatial changes with using empirical Bayesian estimates. Methods We estimated leukemia SMRs with using data of age-sex specific five-year municipal population among 1965-2005 of Japanese Census, age-sex specific cause-specific leukemia deaths of Japanese Vital Statistics, and leukemia deaths of each municipalities. To adjust spatial variations of SMRs in the towns and villages with sparse population, we have applied empirical Bayes method with Poisson distribution model. Results SMRs of leukemia in the study region increased after beginnings of the operation of NPPs. The municipalities located the nearest to NPP had excess SMR (3.69: 95% CI, 3.11-5.56) comparing to farther areas of the prefecture. NPP Reactor type of the study areas was Pressurized Water Reactor (PWR) which released more radioactive substances comparing to Boiling Water Reactor (BWR). The study suggests the relationship between leukemia and NPPs normally operated in Japan.

## **P01.2510. Associations between Urinary Triclosan and Serum Thyroid Hormone Concentrations**

Julianne Skarha

*Julianne Skarha<sup>1</sup>, Lidia Minguéz-Alarcón<sup>2</sup>, Paige Williams<sup>3</sup>, Tim Korevaar<sup>4</sup>, Antonia Calafat<sup>5</sup>, Jennifer Ford<sup>6</sup>, Russ Hauser<sup>4</sup>, Joseph M. Braun<sup>1</sup>*

- 5. US Centers for Disease Control and Prevention, Atlanta, GA, United States.*
- 6. Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

**Abstract:** Introduction: Exposure to the antimicrobial agent triclosan is ubiquitous. In animals, triclosan causes decreases in circulating thyroxine concentrations. However, the effects of triclosan on thyroid hormone levels in humans are unclear. Objective: To estimate the association of urinary triclosan concentrations with thyroid function and autoimmunity in women seeking assisted reproduction treatment in the Environment and Reproductive Health (EARTH) Study. Methods: The EARTH Study is a prospective preconception cohort that has been recruiting Boston area couples since 2004. We conducted a cross-sectional study of 318 EARTH Study women. At baseline, we quantified urinary triclosan concentrations using tandem mass spectrometry and serum thyroid hormone and antibodies levels using immunoassays. We estimated covariate-adjusted differences in thyroid hormones and antibodies with a 10-fold increase in urinary triclosan concentrations using linear regression. We examined effect modification by body mass index (BMI) and infertility diagnosis. We log-transformed thyroid-stimulating hormone, thyroperoxidase (TPOAb), and thyroglobulin (TgAb) and calculated percent differences. Results: Median urinary triclosan concentration was 8.4 µg/L (range: <3 - 2,397 µg/L). Each 10-fold increase in triclosan was inversely associated with free triiodothyronine (fT3) ( $\beta$ : -0.05 pg/mL; 95%CI: -0.1, -0.01), TPOAb (-9%; 95%CI: -18, 0), and TgAb (-12%; 95%CI: -23, 1). Triclosan was inversely associated with fT3 among women with a BMI <25 kg/m<sup>2</sup> ( $\beta$ : -0.08; 95%CI: -0.14, -0.03), but not among women with a BMI  $\geq$  25 kg/m<sup>2</sup> ( $\beta$ : 0.04; 95%CI: -0.04, 0.11) (BMI\*triclosan p-value = 0.03). Infertility diagnosis did not modify the association between triclosan and fT3 (p-value=0.98). Conclusion: Urinary triclosan concentrations were inversely associated with serum fT3, TPOAb, and TgAb concentrations in this cohort. Our findings, consistent with some prior studies, suggest that triclosan may affect thyroid homeostasis.

## **P01.2520. Metal Exposure as a Mixture and Intellectual Function in Adolescence in Bangladesh**

- 6. University of Chicago Research Office, Mohakali, Dhaka, Bangladesh.*

**Abstract:** Background: Exposure to inorganic arsenic (As) is associated with modest deficits in intellectual function in young children. Few studies have examined associations in adolescence or whether co-exposure to other metals such as manganese (Mn), lead (Pb), cadmium (Cd), and selenium (Se) affects the association. Objective: We evaluated whether concurrent exposure to As (as creatinine-adjusted urinary As (UAs/Cr)), the afore-listed metals in blood, and maternal UAs/Cr at baseline, a proxy for peri-natal As exposure, were associated with adolescent intellectual function. Methods: The sample comprises 726 14-16-year-olds whose mothers are participants in the Bangladesh Health Effects of Arsenic Longitudinal Study (HEALS). We used a culturally modified version of the Wechsler Intelligence Scale for Children (WISC-IV) to measure Full Scale raw scores and Bayesian Kernel Machine Regression (BKMR) to investigate the joint effects of the metals mixture on these scores. BKMR uses a flexible kernel function to identify important mixture members while accounting for the correlated exposure structure, to estimate potentially nonlinear exposure-response functions, and to evaluate complex and potentially non-additive interactions. Results: Adolescent UAs/Cr, followed by Cd, were the two most important metals in the mixture, with posterior inclusion probabilities of 95.2% and 83.2%, respectively. Both adolescent UAs/Cr and Cd were significantly associated with decreased Full Scale scores. No significant interactions between metals were observed. The overall mixture (i.e., simultaneous exposure to all metals) was consistently significantly associated with decreased Full Scale scores. Conclusion: Our findings indicate that adolescent exposure to the metals mixtures, and predominantly to As and Cd, may be neurotoxic and deserves more attention.

**P01.2530. Long-Term Quality-Of-Care Summary Score Predicts the Occurrence of Microvascular and Macrovascular Complications in Type 2 Diabetic Patients**

Pi-I Li

*Pi-I Li<sup>1</sup>, How-Ran Guo<sup>2</sup>*

*1. family medicine, Chi Mei Medical Center, Tainan City, Taiwan.*

*2. Department of Environmental and Occupational Health, College of Medicine, National Cheng Kung University, Taiwan, Taiwan.*

**Abstract:** Background: Diabetes requires long-term medical care and management of complications. However, besides the blood glucose level, no reliable method is currently available for linking the quality of care and the development of complications. We therefore developed a long-term quality-of-care score for predicting the occurrence of chronic kidney disease (CKD) and macrovascular diseases in type 2 diabetic patients. Methods: Using Taiwan's Longitudinal Cohort of Diabetes Patients database and the medical records in a medical center, we identified incident type 2 diabetic patients during 1999-2003 and followed them until 2011. A summary score (from 0 to 7) was calculated using process indicators (frequencies of HbA1c, lipid profile testing and urine, and retinal examinations), intermediate outcome indicators (low-density lipoprotein, blood pressure and HbA1c), and comorbidity of hypertension. Cox regression models were used to evaluate the association between the score and the incidence of complications. Results: Of the 2,184 patients enrolled, 598(27.4%) developed CKD after a mean follow-up of 9.3 years. Of the 1,694 patients enrolled, 696 (41.1%) developed macrovascular events after a mean follow-up of 8.6 years. Compared to the risk of developing a CKD event in patients with scores  $\leq 2$ , the risk was 72% lower in those with quality-of-care scores  $\geq 5$  (adjusted hazard ratio [AHR], 0.28; 95% confidence interval [CI], 0.20-0.40) and 36% lower in those with scores between 3 and 4 (AHR, 0.64; 95% CI, 0.53-0.76). Compared to the risk of developing a macrovascular event in patients with scores  $\leq 1$ , the risk was 66% lower in those with quality-of-care scores  $\geq 5$  (AHR, 0.34; 95% CI, 0.25-0.47) and 33% lower in those with scores between 2 and 4 (AHR, 0.67; 95% CI: 0.57-0.78). Conclusion: The score developed in this study had a good association with the risks of macrovascular complications and CKD thus can be applied to guiding the care for patients with type 2 diabetes.

## **P01.2540. Association of Lead Exposure on Cognitive Decline due to Mediation and Interaction with Uric Acid**

Vy Nguyen

Vy Nguyen<sup>1</sup>, Ran Rotem<sup>1</sup>, Monique M. Breteler<sup>2</sup>, Linda Valeri<sup>3</sup>, David Sparrow<sup>4</sup>, Marc Weisskopf<sup>5</sup>

1. *Environmental Health, Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

4. *Veterans Affairs Boston Healthcare System, Boston, MA, United States.*

5. *Environmental Health and Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

**Abstract:** **BACKGROUND:** Low-level cumulative lead exposure has been associated with cognitive decline in adults. Previous studies suggest that lead increases levels of the antioxidant uric acid and that uric acid may also predict changes in cognitive function. We explored whether uric acid mediated or interacted with lead in the association between lead exposure and cognitive decline. **METHODS:** From 1991 to 2002, a subset of the Normative Aging Study cohort of community-dwelling men was assessed for cumulative lead exposure in the tibia and patella bones. The Mini-Mental State Examination (MMSE) was administered as a test of global cognition starting in 1992. We conducted formal mediation analysis using the first bone lead measurement, uric acid concurrent with baseline MMSE, and the difference between the second and baseline MMSE scores, adjusted for age at baseline MMSE, education, serum creatinine, smoking status and pack-years, drinking status, and years between the two MMSE tests. **RESULTS:** 552 men [mean (standard deviation) age: 67.27 (6.52)] took two MMSE tests that were 3.92 (1.80) years apart and had valid bone lead measurements. The total change in MMSE score for an interquartile range (20 µg/g) increase in patella lead was -0.29 (95% confidence interval: -0.49, -0.08) (p=0.007), due mostly to the direct association with lead [-0.25 (-0.44, -0.06) (p=0.01)] when uric acid was set to the mean value; the component due to interaction only was -0.03 (-0.07, 0.004) (p=0.08), due to mediation and interaction was 0.02 (-0.001, 0.05) (p=0.06), and due to mediation only was -0.03 (-0.07, 0.01) (p=0.20). Results with tibia lead were less robust. **CONCLUSIONS:** Prior studies have indicated significant effects of patella lead on cognitive decline, but accounting for uric acid may be needed to understand the full association between lead and cognitive decline.

## **P01.2550. Associations between Parabens and Measures of Metabolic Syndrome in the General Canadian Population**

Joanne Kim

*Joanne Kim<sup>1</sup>, Jonathan Chevrier<sup>1</sup>*

*1. Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, QC, Canada.*

**Abstract:** Background: Metabolic syndrome (MetS) is a cluster of risk factors which increases the risk of developing several chronic diseases. It is defined as having any three of the following risk factors: Abdominal obesity, elevated triglycerides, reduced high-density lipoprotein cholesterol, hypertension, and elevated fasting glucose. Parabens are preservative agents used ubiquitously in cosmetic and personal care products that may increase the risk of MetS due to their endocrine-disrupting properties. We examined if exposure to parabens was associated with MetS or component risk factors in the Canadian general population. Methods: Methyl, ethyl, propyl, and butyl paraben were measured in the urine of participants (n=2564, age 3-79) in Cycle 4 (2014 - 2015) of the Canadian Health Measures Survey (CHMS), a nationally representative biomonitoring survey in Canada. Linear and logistic regression were performed to investigate associations between each individual paraben and MetS, MetS components and related anthropometric measures, adjusted for age, sex, and household income. Results: Due to a high proportion of non-detectable measures for ethyl and butyl paraben (65% and 83%, respectively), only results for methyl and propyl paraben are reported here. Detection rates were high (92% and 79%) and geometric means were 17 ug/L and 2.5 ug/L for methyl and propyl paraben, respectively. Overall, parabens were associated with slightly decreased odds of MetS, and individual MetS components were generally inversely associated with paraben concentrations. However, among children and adolescents (age <18 years), parabens tended to be associated with higher BMI, though not statistically significant. Conclusions: In this cross-sectional analysis, there was little evidence that parabens are associated with MetS. Results considering paraben mixtures and interaction with triclosan will also be presented.

## **P01.2560. Children's Cognitive Function in Relation to Pre- and Postnatal Exposure to Chlordecone**

Christina Xiao

*Youssef Oulhote<sup>1</sup>, Gina Muckle<sup>2</sup>, Christina Xiao<sup>1</sup>, Florence Rouget<sup>3</sup>, Philippe Kadhel<sup>4</sup>, Luc Multigner<sup>4</sup>, Sylvaine Cordier<sup>4</sup>*

*1. Environmental Health, Harvard T. H. Chan School of Public Health, Boston, MA, United States.*

*2. Laval University, Quebec, QC, Canada.*

*3. CHU Rennes, Rennes, France.*

*4. IRSET, Rennes, France.*

**Abstract:** Background: Chlordecone (Kepome) is an organochlorine insecticide that was intensively used in banana fields in the French West Indies, therefore resulting in a widespread contamination of soils, water sources and foodstuff. Despite its proven neurotoxicity at acute exposures, data on its potential neurotoxicity at low exposures in human populations are scarce. Objective: To assess the associations between pre- and postnatal exposures to chlordecone and cognitive function in 7-years children from Guadeloupe. Methods: We examined 377 children from the TIMOUN mother-child cohort in Guadeloupe. Concentrations of chlordecone and other environmental contaminants were measured in maternal blood in the second trimester of pregnancy and in children's blood at age 7 years. Children underwent a battery of neuropsychological testing at 7 years, including the Wechsler Intelligence Scale for Children-IV (WISC-IV). We estimated covariate-adjusted associations between pre- and postnatal chlordecone exposure and child cognitive function using multivariable regression models. We also assessed potential effect modification by sex. Results: Prenatal chlordecone concentrations (geometric mean [GM]: 0.13 µg/L) were higher than at 7 years (GM: 0.06 µg/L). We found no pattern of associations between prenatal chlordecone concentrations and any of the WISC-4 composite or subtest scores. A twofold increase in chlordecone concentrations at 7 years were associated with decreased total IQ scores ( $\beta = -3.3$ ; 95% CI: -6.5, -0.1). This association was mainly driven by decreases in scores of perceptual reasoning ( $\beta = -5.8$ ; 95% CI: -9.9, -1.6). We found no evidence of effect modification by child sex. Conclusions: postnatal concurrent chlordecone exposures, but not prenatal exposures, were associated with lower cognitive function in children from Guadeloupe.

**P01.2570. Investigating the Association between Blood Lead Levels and Alzheimer's Disease Mortality Using NHANES 1999-2008**

Ellen Wells

*Christelene Horton<sup>1</sup>, Hsin-Yi Weng<sup>1</sup>, Ellen M. Wells<sup>1</sup>*

*1. Purdue University, West Lafayette, IN, United States.*

Abstract: Toxicological and epidemiological studies suggest that there is an association between lead (Pb) exposure and Alzheimer's disease (AD); however, few studies have explored Pb and AD mortality. The main objective of this study was to investigate the longitudinal association between blood Pb with subsequent AD mortality. Data from the 1999-2008 National Health and Nutrition Examination Survey (NHANES) and 1999-2014 linked National Death Index files were used for this longitudinal analysis. Analyses included 8084 adults aged  $\geq 60$  years with blood Pb data at the NHANES exam. Cox proportional hazards regression was used to estimate the hazard ratio of AD mortality by blood Pb tertile, adjusting for age, gender, income, race/ethnicity and smoking status. At the time of the NHANES survey, geometric mean blood Pb was 2.45 (95% confidence interval (CI): 2.39, 2.53). N=2227 participants died during follow-up; N=81 died from AD, which is a proportionate mortality of 3.89% (95% CI: 3.00, 5.00). Tertiles of blood Pb were  $< 1.50 \mu\text{g/dL}$ ;  $1.50$  to  $3.00 \mu\text{g/dL}$ ; and  $> 3.00 \mu\text{g/dL}$ . In adjusted models using the lowest blood Pb tertile as the referent, participants in the second and third blood Pb tertile had 1.61 (95% CI: 0.84, 3.11) and 1.74 (95% CI: 0.86, 3.52) times the risk of AD mortality, respectively. A limitation of this analysis is that the true burden of AD may not be well represented by mortality, as those with AD may die from other causes. However, this study has several strengths: it is longitudinal, uses a large sample, and is representative of the United States population. Although it was not statistically significant, results from this analysis suggest that there is an association of increased Pb with AD mortality. Further research in this area is recommended.

**P01.2580. Pesticide and Acute Asthma Attacks in California, Usa in 2005 to 2011: A Bidirectional Symmetric Case-Crossover Study**

Marcela Entwistle

*Hamed Gharibi<sup>1</sup>, Vicente A. Ramirez<sup>1</sup>, Marcela R. Entwistle<sup>1</sup>, Chia Thao<sup>1</sup>, Ricardo Cisneros<sup>2</sup>*

*1. School of Social Sciences, Humanities and Arts, University of California, Merced, Merced, CA, United States.*

*2. Health Science Research Institute, University of California, Merced, Merced, CA, United States.*

Abstract: In this study, a bidirectional symmetrical case-crossover method was applied to analyze the data obtained from Emergency Department Visits for asthma occurrence and publicly available EPA emissions data for methyl bromide and 1,3-dichloropropene in California, USA between 2005 and 2011. The effect modification of parameters through stratified analyses by sex (female, and male), race (Whites, Blacks, Hispanics, and Asian) and age (2-5, 6-18, 19-40, 41-64 and  $\geq 65$ ) is considered. In this work, 8566 individuals within the area under the study visited the emergency departments due to asthma attacks between 2005 and 2011. In addition, biweekly samplings of the concentration of the two pesticides, PM<sub>2.5</sub>, NO<sub>2</sub>, NO, SO<sub>2</sub>, and O<sub>3</sub> and measures of relative humidity, temperature, and pressure were collected for 14 sites. Based on the results, methyl bromide is not positively associated with the occurrence of acute asthma attack in California, USA between 2005 and 2011. For 1,3-dichloropropene, a 0.01 ppb increase in its exposures during the event day was associated with a 4.9% increase in asthma ED visits. Stratifying for race and sex showed that the effect is nearly similar among different races and sex. However, it was found that those who were 65 years or older during the time period of the study were affected more by the exposure to methyl bromide, than the other age groups. It can be implied from the findings in this study that the pesticides, as toxic air pollutants, are related to asthma attacks; however, there is a lack of enough data to delve into this issue.

## **P01.2590. Case-Control Study on Lung Cancer and Residential Radon in South Korea**

Min Heui Yu

*Min Heui Yu<sup>2</sup>, Hye Sim Kim<sup>1</sup>, Dae Ryong Kang<sup>3</sup>*

*1. Center of Biomedical Data Science, Yonsei University Wonju College of Medicine, Wonju, Korea (the Republic of).*

*2. Department of Biostatistics, Yonsei University Wonju College of Medicine, Wonju, Korea (the Republic of).*

*3. Institute of Genomic Cohort, Yonsei University Wonju College of Medicine, Wonju, Wonju, Korea (the Republic of).*

**Abstract:** Background/Purpose: Radon exposure is a major risk factor of lung cancer. The World Health Organization (WHO) defines radon as the major cause of lung cancer following smoking, with 3-14% of lung cancer occurring worldwide. The WHO recommends radon concentration lower than 100 Bq/m<sup>3</sup>. In recent years, most of the advances in personalized therapy in Non Small Cell Lung Cancer (NSCLC) patients also occurred in non-smokers. The purpose of this study was to assess the effect of residential radon exposure on the risk of lung cancer in non-smokers and female in Korea. Method: This study was designed a multicenter hospital-based case and community-based control study in Korea. The seasonal correction was applied to the measured values of the radon concentration in both the case and control groups. Total 1053 (481 cases and 572 controls) were included in the data. 1:1 propensity score matching was performed considering age, sex, smoking status, involuntary smoking status, number of ventilation, impervious ratio, and type of house. Odds ratio for the risk of lung cancer according to the status of smoking and sex were performed using logistic regression and nonlinear regression analysis. Result: After seasonal correction, mean and standard deviation of radon concentration was 69.67±49.99 Bq/m<sup>3</sup> in cases and 60.45±44.57 Bq/m<sup>3</sup> in controls. 200 cases and 200 controls were matched and 51% were females. When we analyzed radon concentration as continuous, we observed an adjusted odds ratio of 1.92(95% CI : 1.13-3.25) in never-smokers and 1.19(95% CI : 0.68-2.09) in smokers. The adjusted odds ratio was 1.93(95% CI : 1.09-3.43) in females and 1.19(95% CI : 0.72-7.98) in males. Conclusion: Residential radon increases lung cancer risk among non-smoker and female. Therefore, intensive investigation of the relationship between lung cancer risk and smoking status or sex should be conducted to elucidate this results.

## **P01.2600. Five-Year Lung Cancer Mortality Risk Analysis and Topography in Xuan Wei: A Spatio--Temporal Correlation Analysis**

Jinhui Li

*Jinhui Li<sup>1</sup>, Wenbo Guo<sup>2</sup>, Jinjun Ran<sup>1</sup>, Robert Tang<sup>1</sup>, Hualiang Lin<sup>4</sup>, Yongchun Zhou<sup>3</sup>, Yunchao Huang<sup>3</sup>, Linwei Tian<sup>1</sup>, Lung-Chi Chen<sup>5</sup>*

- 3. The Third Affiliated Hospital of Kunming Medical University , Kunming, China.*
- 4. Sun Yat-sen University, Guangzhou, China.*
- 5. New York University , New York, NY, United States.*

**Abstract:** Background: In Xuan Wei, the lung cancer mortality rate is five times higher than the country average, and continues to increase despite interventions to reduce indoor coal burning air pollution. This study aims to investigate the spatial and temporal trends of lung cancer in Xuan Wei from 2011 to 2015. Methods: The pooled data of lung cancer registries for all the towns in Xuan Wei was first collected. The spatial distributions of local relative production volumes and mine deposits were acquired. The spatial autocorrelation was explored by spatio--temporal GIS approach. Four sets of spatial analysis and spatial statistics were applied: 1) hotspot analysis and 3D-geographical visualization, 2) a spatially weighted sum, 3) spatial interrelation between coal mines and lung cancer mortality, and 4) a geographically weighted regression model. Results: Females exhibited higher lung cancer mortality than males, with an increasing trend observed for both sexes over time. The incidence rate in Laibin Town was the highest in Xuan Wei for each year. Higher mortality was found in counties with coal industries, especially for those over 30+ years old. The village-level mortality showed clustered trends. The hotspot analysis and 3D-geographical visualization demonstrated increasingly concentrated patterns around Laibin, Shuanglong, and Longchang. The mapped health risks showed the geographical pattern of potential lung cancer health risks from the coal mine, and spatio--temporal variations were found in the five-year period for both sexes. Conclusions: Lung cancer mortality has increased continuously since the third mortality survey in Xuan Wei. Geographically, the locations for different kinds of mines have interrelation with the lung cancer mortality in Xuan Wei. Specific exploration targeted at the local environmental health related to coal burning indoor air pollution is warranted.

## **P01.2610. Serum Concentrations of Polychlorinated Biphenyls and Risk of Uterine Leiomyomata**

Lauren Wise

*Amelia K. Wesselink<sup>1</sup>, Traci N. Bethea<sup>2</sup>, Jennifer Weuve<sup>1</sup>, Russ Hauser<sup>3</sup>, Paige Williams<sup>4</sup>, Theodore M. Brasky<sup>5</sup>, Michael D. McClean<sup>6</sup>, Donna D. Baird<sup>7</sup>, Lauren A. Wise<sup>1</sup>*

**Abstract:** Polychlorinated biphenyls (PCB) are persistent endocrine-disrupting chemicals with varying types and degrees of hormonal activity. Animal and human evidence suggests that sex steroid hormones are involved in the etiology of uterine leiomyomata (UL), common gynecologic neoplasms that can cause severe reproductive morbidity. Three retrospective studies have shown positive associations between PCB exposure and UL risk. We performed a case-cohort analysis examining the association between serum concentrations of PCBs and risk of UL in a cohort of premenopausal Black women from the Detroit, Michigan metropolitan area (2011-12). Eligible women were age 23-34 years and had no prior diagnosis of UL, autoimmune disease, or cancer. We collected demographic, behavioral, dietary, and medical data via self-administered questionnaires, telephone interviews, and in-person clinic visits. To identify UL, participants underwent transvaginal ultrasounds at baseline and at 20- and 40-month follow-ups. We collected non-fasting blood samples from a random subset of 454 participants at baseline, in which we measured 24 PCB congeners at the Centers for Disease Control and Prevention. We lipid-adjusted PCB concentrations and set values below the limit of detection (LOD) to LOD/sqrt(2). We examined total PCB concentration and groupings determined by hormonal activity. We used Cox proportional hazards regression models to estimate adjusted incidence rate ratios (IRR) and 95% confidence intervals (CI). Over 40 months of follow-up, we identified 132 incident UL cases. IRRs for total serum PCB concentrations of 30-39, 40-49, 50-59, and  $\geq 60$  vs.  $< 30$  ppb were 1.06 (95% CI: 0.67-1.66), 1.20 (95% CI: 0.69-2.08), 0.55 (95% CI: 0.21-1.41), and 0.87 (95% CI: 0.48-1.58), respectively. Estrogenic and anti-estrogenic PCB concentrations were not associated with UL risk. This study does not support the hypothesis that serum concentrations of PCBs measured in adulthood increase risk of UL among Black women.

## **P01.2624. Sun Avoidance and the Risk of Developing Breast Cancer: A Systematic Review and Meta-Analysis**

Troy Hillier

*Troy Hillier<sup>1</sup>, Dylan E. O'Sullivan<sup>1</sup>, Darren R. Brenner<sup>3</sup>, Cheryl Peters<sup>2</sup>, Will King<sup>1</sup>*

*3. Oncology and Community Health Sciences, University of Calgary, Calgary, AB, Canada.*

**Abstract:** Background: A relationship has been hypothesized between moderate solar ultraviolet radiation (UVR) exposure and breast cancer. This hypothesis centers on the anti-proliferative and apoptotic properties of vitamin D, as well as increases in nocturnal melatonin concentrations which have been shown to slow cellular proliferation. To date, the literature on the effects of exposure to UVR and breast cancer risk have not been systematically reviewed and synthesized. Furthermore, the effects of sun avoidance (low amounts of time spent in the sun) in different exposure windows (adolescence vs. a period relevant to diagnosis) have not been compared. Methods: We conducted a systematic review and meta-analysis to investigate the association between sun avoidance (defined as less than an hour of sun per day) and the risk of developing breast cancer. Associations were estimated using random effects models. Heterogeneity was investigated through subgroup analyses and I<sup>2</sup> statistics. Results: Seven studies were included in this review with the majority (n=5) being conducted in Canada or the US. We observed an increased risk of breast cancer for individuals obtaining less than an hour of sun exposure per day during summer months compared to individuals that obtained greater than an hour (pooled relative risk (RR) = 1.15; 95% CI: 1.09-1.20). Heterogeneity among this body of literature was minimal (I<sup>2</sup> = 2.7%) Among studies that measured sun exposure over different life periods, sun avoidance during adolescence appeared to confer a qualitatively greater risk of breast cancer than that closer to diagnosis (pooled RR = 1.18; 95% CI: 1.05-1.30 vs. 1.05; 95% CI: 0.88-1.25). Conclusion: This is the first meta-analysis to estimate the risk of developing breast cancer associated with sun avoidance. The results of this study suggest that obtaining less than one hour of sun per day during summer months, especially in adolescence, could increase the risk of developing breast cancer.

Abstract: Ingested arsenic (As) undergoes methylation generating mono-methyl (MMA) and dimethyl (DMA) arsenicals; this facilitates urinary As (uAs) elimination and may reduce As toxicity. Higher MMA% in urine has been associated with higher risk for cardiovascular disease and cancer. Decreased MMA%, however, has been associated with increased risk of diabetes-related outcomes in populations from the US and Mexico. Our objective was to estimate the association between uAs and blood As (bAs) metabolites with BMI in adults from Bangladesh. Of the 610 participants in the Folic Acid and Creatine Trial (FACT) study, 528 participants (275 men and 253 women) had complete baseline data on BMI, bAs, uAs, plasma folate, cigarette use, and other factors of interest. Our preliminary results from the FACT dataset show the median inorganic arsenic (iAs) %, MMA% and DMA% species in urine were 13.2, 14.2, and 71.8 in men and 13.5, 10.7 and 75.7 in women. In blood, the medians for iAs%, MMA% and DMA% were 26.8, 45.1 and 28.1 for men and 26.8, 43.9 and 29.0 for women. Overall, the data revealed no association between As metabolites and BMI in men, but found an association in women. For uAs metabolites, the adjusted mean difference (95% confidence) in BMI for a 5% difference in MMA% was -0.74 (-1.24, -0.24) kg/m<sup>2</sup> and for a 5% difference in DMA% it was 0.45 (0.17, 0.74) kg/m<sup>2</sup>. The corresponding data for bAs metabolites were -0.22 (-0.65, 0.2) and 0.41 (0.04, 0.77), respectively. For both urine and blood metabolites, higher DMA% was associated with higher BMI levels in women. While the reason underlying the sex-specific findings is unclear, we speculate that it may be related to body fat, which is greater among women in Bangladesh. In future studies, we plan to pool multiple studies from Bangladesh to evaluate the consistency of these findings.

## **P01.2640. Cumulative Exposure to Organic Pollutants in French Children Assessed by Hair Analysis**

Alba Iglesias Gonzalez

*Alba Iglesias Gonzalez<sup>1</sup>, Emilie Hardy<sup>1</sup>, Brice M. Appenzeller<sup>1</sup>*

*1. Human Biomonitoring Research Unit - Department of Population Health, Luxembourg Institute of Health, Luxembourg, Luxembourg.*

Abstract: In 2014, the total quantity of pesticide sales in the EU-28 amounted to close to 400'000 tons, with France as the second pesticide consumer with 75'000 tons used for agriculture (Eurostat 2017). Children represent one of the most vulnerable category of the population. Chronic exposure to pesticides has been proven in the literature to be highly related with developmental issues as well as with several diseases such as leukaemia. Although a few studies based on biomonitoring approaches were conducted in France to assess pesticide exposure in adults or pregnant women, studies conducted on children are still absent. Hair analysis has been proven to give more accurate and reliable information than urine and blood, becoming a promising matrix for biomonitoring of chronic exposure. Moreover, pesticide concentration in hair is correlated to the level of exposure. In the present study hair samples were collected from 142 French children from different areas: rural (n=36), urban (n=72), wine production (n=25) and a remote island (n=9). Hair samples were analysed with an analytical method (GC/MS-MS) allowing for the detection of 55 currently used and banned pesticides, 4 PCBs and 5 brominated flame retardants. All the samples tested positive for at least 9 and up to 37 compounds (average =21). Three organochlorine pesticides, 1 organophosphate metabolite and 1 pyrethroid metabolite were detected in all the samples. The highest concentration was observed for permethrine (>5000 pg/mg). The highest number of chemicals was observed in children living in urban areas (mean = 52) and the lowest in children from the remote island (mean = 28). Although these results cannot be considered representative of all French children, they demonstrate the diversity in the exposure between different areas. These results also highlighted the cumulative exposure to pollutants from different chemical families and for most of them provide the first values of concentration in children's hair.

## **P01.2650. Human Urinary Biomarkers of Exposure to the Plasticizer Deha**

Alexandra Nehring

Abstract: Di (2-ethylhexyl) adipate (DEHA) is predominantly used as plasticizer in PVC consumer products, but can also be used in nitrocellulose base coatings and synthetic rubbers. Blends of DEHA with general-purpose phthalates improve low-temperature flexibility for consumer goods like garden hoses, gaskets and tubing. DEHA is also used to substitute Di(2-ethylhexyl)phthalate (DEHP) in some medical applications like e.g. nutrition transfer systems or tubing for hemodialysis. The use of DEHA for food contact materials like flexible PVC cling film is approved in several parts of the world (e.g. Europe, North America/Canada, Asia). All of these applications imply likely exposures of the general population. The former European Scientific Committee on Food evaluated the data available on DEHA in 1994 and derived a tolerable daily intake (TDI) of 0.3 mg/(kg bw\*d). We developed an online-SPE-LC-MS/MS method with isotope dilution to investigate the metabolism of DEHA and urinary excretion kinetics of its metabolites. 4 volunteers were dosed orally with 10 mg DEHA. Urine samples were consecutively collected for 48 hours after dosage. Following oral uptake, DEHA is quickly metabolized and excreted in urine as adipic acid, which, however, is not a specific biomarker. The side chain oxidized monoester metabolites of DEHA in urine, 2-ethyl-5-hydroxyhexyl adipate (5OH-MEHA), 2-ethyl-5-oxohexyl adipate (5oxo-MEHA), and 5-carboxy-2-ethylpentyl adipate (5cx-MEPA) were identified as specific and robust biomarkers. Urinary conversion factors were also established, whereby 5cx-MEPA, the major specific metabolite, represented approximately 0.2% of the oral dose in urine. We applied the specific DEHA biomarkers in a pilot biomonitoring study on German adults and pregnant Brazilian women and were able to detect all three biomarkers in the urine samples with the highest prevalence for 5cx-MEPA.

## **P01.2670. The Precision and Accuracy of Urinary Creatinine Analysis for Correction of Urine Dilution in Biological Monitoring Measurements**

Che-Jung Chang

*Che-Jung Chang<sup>1</sup>, Priya D'Souza<sup>1</sup>, P. Barry Ryan<sup>1</sup>, Dana Barr<sup>1</sup>*

*1. Environmental Health Science , Emory, Atlanta, GA, United States.*

Abstract: Biomonitoring has been widely used to assess environmental exposure, and spot urine is commonly studied due to its easy sample collection. The variability of urine dilution has been crucial for assessing the exposure magnitude. Previous studies indicated that creatinine-adjusted concentrations are better correlated with the parent chemical concentrations in blood, plasma or serum than unadjusted concentrations. More recent studies have documented problems with creatinine-adjustment in pregnant women and diverse populations because creatinine varies with age, gender, race, body size, and diet. In addition to the inter- and intra-person variability in creatinine, we found significant variability in the testing methods and the testing laboratories. Two immunoassays gave decidedly different concentrations on the same samples in two different laboratories and even had a greater than 35% bias on NIST Standard Reference Materials. In an attempt to standardize the creatinine measurements, both laboratories adopted the same immunoassay. The inter-laboratory relative percent differences (RPD) ranged from 0.3-13.4% with 5.2% median, and the values determined in each laboratory were highly correlated (Pearson correlation coefficient:  $r=0.98$ ). Although the results were correlated and relatively precise, 15% biases were found between laboratories with values determined by laboratory B being uniformly higher. The directional significant differences were confirmed by paired t-test ( $p$ -value $<0.001$ ). Thus, a systemic error can occur among different laboratories which might alter the point estimates of central tendency and percentile concentrations. The results show that in addition to the inherent limitations of biological variation in using creatinine-adjustment in biomonitoring, laboratory error from non-standardized measurements can further introduce variation. Taken together, we suggest that the standardized creatinine measurement or cross-laboratories validation is needed.

## **P01.2680. Serum Metabolomics of Children Exposed to Carcinogenic Pollutants from Petrochemical Industries**

Chi-Hsin Chen

*Chi-Hsin S. Chen<sup>1</sup>, Tzu-Hsuen Yuan<sup>1</sup>, Chang-Chuan Chan<sup>1</sup>*

*1. Institute of Occupational Medicine and Industrial Hygiene, National Taiwan University, Taipei, Taiwan.*

**Abstract:** Background: Petrochemical industries emit multiple carcinogenic pollutants that could induce common complex diseases, warranting a systemic evaluation of exposures and health impacts on nearby communities. Methods: We applied serum metabolomics approach to identify potential multiple pollutants exposure-induced metabolic changes that could contribute to disease onset. 106 children (aged 9-15) who have lived for more than 5 years near a petrochemical complex in Taiwan were selected. Subjects were defined as high or low exposure group according to distance from their home locations to two main emission points of the complex, and urine concentrations of exposure biomarkers. Individual exposure levels of multiple carcinogenic pollutants including urine heavy metals and 1-hydroxypyrene (1-OHP) were analysed using inductively coupled plasma mass spectrometry and high performance liquid chromatography, respectively. Serum targeted metabolites, lipidomic profiles, and 30 acylcarnitines were analysed using ultra performance liquid chromatography coupled with quadrupole time-of-flight tandem mass spectrometry. Results: Significantly increased urine concentrations of 1-OHP, vanadium, arsenic, strontium, cadmium, and thallium were found in high exposure group compared to low exposure group. Targeted metabolomics showed 6 upregulated metabolites and 3 downregulated metabolites in high exposure group compared to low exposure group. Lipid profiles showed clear separation between the two exposure groups, and identified 45 potential exposure-related lipids. 8 acylcarnitines were significantly decreased in high exposure group compared to low exposure group, and 2 were significantly increased. Conclusions: Our results demonstrate how a mixture of carcinogenic pollutants emitted from petrochemical industrial sources increased internal exposures in nearby populations in a distance-to-source-related manner, and induce metabolomic changes that could lead to adverse health effects in children.

## **P01.2690. Pesticide Urinary Metabolite Levels in Asthmatic Children Residing in Subsidized Housing**

Derek Werthmann

*Derek W. Werthmann<sup>1</sup>, Dan Stout<sup>2</sup>, Nicolle S. Tulve<sup>2</sup>, Gary Adamkiewicz<sup>3</sup>, Felicia Rabito<sup>1</sup>*

*2. ORD/NERL, U.S EPA, Research Triangle Park, NC, United States.*

*3. Environmental Health, Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

**Abstract:** We examined urinary pesticide (UP) metabolite levels in asthmatic children residing in subsidized housing in New Orleans, Louisiana and compared these levels between children residing in green and non-green housing. Morning void samples were collected from 68 children (aged 7-12 years) at three time points between 2014 and 2016. Ninety-seven percent of children provided three urine samples. Urine samples were analyzed for seven pesticide metabolites (3 organophosphates: TCPY, IMPY, PNP; 3 pyrethroids: 4-F-3-PBA, 3-PBA, trans-DCCA; and 1 herbicide: 2,4-D). Metabolites were creatinine-adjusted and natural log transformed. Children were classified as residing in green housing if the home was constructed with low VOC materials and utilized integrated pest management. Differences in metabolite levels were analyzed using generalized estimating equations. Four metabolites (2,4-D, TCPY, 3-PBA, PNP) were detected in >90% of samples. IMPY was detected in 52% of samples, and 4-F-3-PBA and trans-DCCA were not frequently detected (<9%, <13%, respectively). There were no statistically significant differences in UP level at any time point. There were lower levels of 4-F-3-PBA ( $\beta=-1.23$ ,  $p=0.11$ ), TCPY ( $\beta=-0.05$ ,  $p=0.63$ ), and PNP ( $\beta=-0.01$ ,  $p=0.93$ ) for children living in green housing. 2,4-D ( $\beta=0.09$ ,  $p=0.43$ ), 3-PBA ( $\beta=0.08$ ,  $p=0.63$ ), IMPY ( $\beta=0.02$ ,  $p=0.90$ ), and trans-DCCA ( $\beta=0.37$ ,  $p=0.07$ ) levels were higher for those in green housing. None of the differences in housing type reached statistical significance. In models examining the interaction between housing type and time, there were no statistically significant differences between green and non-green housing at any time point. These results suggest that asthmatic children residing in subsidized housing in New Orleans are chronically exposed to low levels of pesticides resulting in limited variability of UP metabolite. We found no significant differences in UP levels between children residing in green housing compared to non-green housing.

## **P01.2700. The Association between Olfactory and Cognitive Function Tests with Aluminum Biomarkers in an Occupationally Exposed Population from Zunyi, China**

Hasan Zainab

*Hasan Zainab<sup>1</sup>, Danelle Rolle-McFarland<sup>1</sup>, Yingzi Liu<sup>2</sup>, Farshad Mostafaei<sup>3</sup>, Wei Zheng<sup>1</sup>, Linda Nie<sup>1</sup>, Ellen M. Wells<sup>1</sup>*

*1. Health Sciences, Purdue University, West Lafayette, IN, United States.*

*2. Willis-Knighton Cancer Center, Shreveport, LA, United States.*

*3. Wisconsin Medical School, Milwaukee, WI, United States.*

**Abstract:** High aluminum (Al) exposure has been associated with neurological and olfactory disorders; however, the degree to which Al damages the brain remains unknown. Therefore, the aim of this cross-sectional study of factory workers from Zunyi, China was to determine the relationship between cognitive and olfactory function with three Al biomarkers: bone (BnAl) (n=43), blood (WbAl) (n=60) and fingernail (FnAl) (n=61). Olfactory function was assessed with the University of Pennsylvania Smell Identification Test and cognitive function was assessed with the WHO/UCLA Auditory Verbal Learning Test (AVLT). Bone measurements were taken noninvasively with a compact in-vivo neutron activation analysis system and both WbAl and FnAl samples were analyzed using inductively coupled plasma mass spectrometry. Other variables were self-reported via questionnaire. Linear regression models adjusted for age, education, factory, current alcohol consumption and current smoking status. Median Al values were: 235 µg/L (interquartile range (IQR)=72) WbAl; 35 µg/g (IQR=50) FnAl and 15 µg/g (IQR=28) BnAl. Unadjusted regressions indicated a significant decrease in olfactory function related to an increase in Al for both FnAl ( $\beta=-0.045$ , 95% confidence interval (CI)=-0.086, -0.004) and WbAl ( $\beta=-0.011$ , 95% CI=-0.018, -0.004). Adjusted regression models showed a significant association between increasing WbAl and increased AVLT intrusions (worse performance) for trial 3 ( $\beta=-1.002$ ,  $p=0.004$ ) and 7 ( $\beta=-2.473$ ,  $p=0.002$ ). Our study found some, but not all, measures of short-term Al exposure were significantly associated with olfactory and cognitive tests. None of the test outcomes were significantly associated with BnAl, a novel measure of cumulative Al exposure. Larger studies are needed to definitively confirm the lack of association between BnAl with cognitive and olfactory function.

**P01.2710. Association of Urinary Phthalate Metabolites and Phenolics with Metabolic Syndrome Related Biomarkers among Reproductive Age Women of Korea**

**Abstract:** Endocrine disrupting chemicals (EDCs) such as phthalates and phenolics have been associated with metabolic syndrome (MetS) among humans. However, limited information exist on relationship of EDCs with adipokines and lipid profiles in humans. In the present study, reproductive age women (n=516, aged 20s to 40s) were recruited from major cities throughout the Korea between 2015 and 2016, and measured for phthalate metabolites and environmental phenols in urine samples. MetS related biomarkers such as adiponectin, leptin, glucose, insulin, high density lipoprotein (HDL)-cholesterol, triglycerides (TG), and total cholesterol (TC) were also analyzed in serum. Multivariable linear regression was used to assess the association between urinary chemical profile and the MetS related biomarkers. Urinary di-(2-ethylhexyl) phthalate metabolite ( $\Sigma$ DEHP), mono-methyl phthalate (MMP), mono-benzyl phthalate (MBzP), and bisphenols S (BPS) levels were positively associated with glucose after adjusting for age, body mass index (BMI), alcohol consumption status, smoking, and urinary creatinine. Urinary DEHP and MBzP levels were positively associated with adiponectin, but urinary MMP and DEHP metabolite levels were negatively associated with TC after adjusting for the covariates. MMP, ethyl paraben (EtP), propyl paraben (PrP), and benzophenone-1 (BP-1) were negatively associated with BMI after adjusting for age, alcohol consumption status, smoking, and urinary creatinine. These observations showed that exposure to phthalates and phenolics may be associated with MetS among reproductive age women. Further studies on possible interaction among the chemicals and replication in other populations are warranted.

## **P01.2720. Cadmium and Kidney Function in the U.S. Population: Impact of Sex, Diabetes and Hypertension**

Jessica Madrigal

*Jessica Madrigal<sup>1</sup>, Ana Ricardo<sup>2</sup>, Victoria Persky<sup>1</sup>, Mary Turyk<sup>1</sup>*

*1. School of Public Health, University of Illinois at Chicago, Chicago, IL, United States.*

*2. Division of Nephrology, Department of Medicine, University of Illinois at Chicago, Chicago, IL, United States.*

**Abstract:** Exposure to cadmium has been associated with nephropathy and the development of diabetes and hypertension, but may be an underexplored risk factor for decreased kidney function among people with preexisting diabetes and/or hypertension. Our objective was to evaluate sex, diabetes, and hypertension status as effect modifiers of the association between cadmium exposure and kidney function. We used data from adults in the National Health and Nutrition Examination Survey (NHANES) 2007-2012 cycles. Multivariable adjusted linear and logistic regression models were used to conduct a cross-sectional analysis of the association between blood levels of cadmium and estimated glomerular filtration rate (eGFR), urine albumin to creatinine ratio (UACR), low eGFR (eGFR <60 mL/minute/1.73m<sup>2</sup>), and albuminuria (UACR > 30 mg/g). Interaction terms were evaluated for cadmium level and sex, diabetes, and hypertension. Final models were stratified by sex and existing diabetes and hypertension status. Cadmium levels were negatively associated with eGFR, with significant interactions for cadmium and sex, cadmium and hypertension, and cadmium, sex, and hypertension. The association between high cadmium exposure and low eGFR was strongest among females with hypertension and diabetes ( $\beta = -4.3$  (95% CI -7.6 to -0.91)) or hypertension alone ( $\beta = -2.4$  (95% CI -4.5 to -0.42)). Among males with diabetes, exposure was associated with lower eGFR ( $\beta = -5.9$  (95% CI -10.5 to -1.3)). Among females, exposure was associated with a 70% increase in the odds of low eGFR (OR 1.7 (95% CI 1.4 to 1.9)). The odds of low eGFR were increased among those with hypertension (OR 1.7 (95% CI 1.4 to 2.0)) compared to those without (OR 1.2 (95% CI 0.93 to 1.5)). Our results provide evidence that the magnitude of these associations differs by sex and may vary by preexisting diabetes and hypertension status. Future investigations should be sex-specific and further environmental contamination from cadmium must be prevented.

## **P01.2740. Human Urinary Biomarkers of Exposure to the UV Filter Avobenzone**

Kathrin Papadopoulos

*Kathrin Papadopoulos<sup>1</sup>, Daniel Bury<sup>1</sup>, Heiko Hayen<sup>2</sup>, Tobias Weiss<sup>1</sup>, Thomas Brüning<sup>1</sup>, Holger M. Koch<sup>1</sup>*

*1. Institute for Prevention and Occupational Medicine of the German Social Accident Insurance - Institute of the Ruhr-Universität Bochum (IPA), Bochum, Germany.*

*2. Institute of Inorganic and Analytical Chemistry, University of Münster, Münster, Germany.*

Abstract: Avobenzone (butyl methoxydibenzoylmethane) is a UV-A filter widely used in personal care products (sunscreens and other cosmetics), with maximum permitted concentrations of 3% in the U.S. and 5% in the European Union. Due to its widespread use in consumer products, exposure of the general population is probable. Therefore, avobenzone was selected as a substance of concern within the scope of a large scale cooperation project between the German Ministry for the Environment (BMU), German Chemical Industry Association (VCI) and the German Environment Agency (UBA). This project has the aim to establish new human biomonitoring (HBM) methods for 50 emerging chemicals. For the identification of avobenzone metabolites as suitable biomarkers of exposure, we orally dosed five volunteers with neat avobenzone (5 mg). Consecutive and complete urine samples were collected over a period of 48 h post dose. The urine samples were analyzed with a data-mining software-assisted suspect screening approach, using liquid chromatography-high resolution mass spectrometry (LC-HRMS and -MS/MS). A variety of specific avobenzone metabolites (including hydrogenated, hydroxy, and carboxylic acid metabolites) was tentatively identified and semi-quantitative elimination kinetics for each metabolite were obtained. We selected the four most promising urinary metabolites as exposure biomarker candidates for HBM method development. We currently investigate human metabolism quantitatively, derive urinary metabolite excretion factors, and analyze samples from sunscreen users and the general population (LC-QqQ-MS/MS using analytical standards and stable isotope labeled internal standards) to assess the suitability of these metabolites as avobenzone exposure biomarkers. It is then planned to use these biomarkers in large scale population studies such as the German environmental survey (GerES) or the German Environmental Specimen Bank (ESB).

**P01.2750. Investigating the Association of a Biomarker of Triphenyl Phosphate Exposure with Metabolic Health in the U.S. Population**

Lariah Edwards

*Lariah M. Edwards<sup>1</sup>, Jennifer Schlezinger<sup>1</sup>, Thomas F. Webster<sup>1</sup>, Junenette L. Peters<sup>1</sup>*

*1. Environmental Health, Boston University School of Public Health, Boston, MA, United States.*

**Abstract:** Background: Triphenyl phosphate (TPHP) is a flame retardant and plasticizer found in commercial and consumer products. The primary metabolite, diphenyl phosphate (DPHP), occurs widely in urine samples. There is a lack of epidemiological data to support the toxicological evidence regarding TPHP's role in disrupting metabolism. Objective: We evaluated the association of urinary DPHP with fasting plasma glucose, hemoglobin A1c, homeostatic model assessment of insulin resistance, 2-hour oral glucose, and waist circumference using data from NHANES 2013-2014. Methods: Data were available for 1,201 adults aged 20 years and up with no prior diabetes diagnosis. We used two methods to account for urine dilution of DPHP: 1) urinary excretion rate (UER) of DPHP estimated by multiplying urine concentration by urine flow rate; 2) a recently proposed method of covariate-adjusted creatinine standardization with less potential bias than traditional creatinine correction. We assessed the relationship between quartiles of urinary DPHP and each outcome using multiple linear regression models, adjusting for confounders. Results: Preliminary analyses of males yielded no clear trends across quartiles for the outcomes, but results were elevated in some quartiles. Males in Q4 of creatinine standardized DPHP had higher waist circumference than males in Q1 ( $\beta= 7.70$ , 95% CI: 3.2, 12.2). Males in Q2 of DPHP had 9.4% higher fasting plasma glucose compared to males in Q1 ( $\beta= 0.094$ , 95% CI: 0.019, 0.17). Use of UER DPHP yielded similar results with waist circumference, although only marginally significant (Q4:  $\beta= 5.22$ , 95% CI: -0.37, 10.8). As toxicological data suggest the potential for effect measure modification by menopause status in women and diet, we are conducting additional sub-group analyses. Conclusion: In men, urinary DPHP was positively associated with certain measures of metabolic disruption, but with no clear trends. Analysis of potentially more susceptible sub-groups is underway.

**P01.2760. Correlation over Time of Toenail Metals among Participants in the VA Normative Aging Study from 1992 to 2014**

Marc Weisskopf

**Abstract:** Background Scientists use biomarkers to evaluate metal exposures. One biomarker, toenails, is easily obtained and minimally invasive, but less commonly used as a biomarker of exposure. Their utility will depend on understanding characteristics of their variation in a population over time. The objective of our study is to describe the correlation of toenail metal levels many years apart among participants in the VA Normative Aging Study (NAS). Methods Toenail clippings from 825 participants of the NAS from year 1992 to 2014 were analyzed for lead (Pb), Arsenic (As), Cadmium (Cd), Manganese (Mn), and Mercury (Hg). We utilized linear mixed models to assess correlation between toenail metal concentrations in multiple toenail samples from the same subject collected years apart and identified the optimal covariance pattern by likelihood ratio tests and Akaike's information criterion (AIC). Correlations among different metals were described using Spearman correlations. Results The average number of times toenail samples were collected from each subject ranged from 1.63 (Hg) to 2.04 (As). The average number of years between toenails collected per subject ranged from 4.73 (SD=2.44) (Mn) to 5.35 (SD=2.69) (Hg). Metal concentrations had slightly different correlation patterns over time, although for all metals correlations decreased with increasing time between samples. Estimated correlations over a 3-year span were highest for toenail Pb (0.68) and Hg (0.67), while As, Cd, and Mn had lower correlations of 0.49, 0.44, and 0.47, respectively. Even across a six-year span, the lowest correlation was 0.35 (Cd). Conclusion Our results suggest that Pb, As, Cd, Mn, and Hg levels from toenail clippings can reasonably reflect exposures over several years in elderly men in the NAS. Even across six years, toenail metal levels were generally well correlated among NAS participants. As such, they may be useful as biomarkers of exposure in epidemiological studies of similar populations.

## **P01.2810. Household Exposures, Glutathione S-Transferase Genes and Asthma Risk in Middle-Age**

Xin Dai

*Xin Dai<sup>1</sup>, Shyamali Dharmage<sup>1</sup>, Haydn Walters<sup>2</sup>, Adrian Lowe<sup>3</sup>, John Burgess<sup>1</sup>, Aung K. Win<sup>1</sup>, Michael J Abramson<sup>3</sup>, Dihn Bui<sup>1</sup>, Caroline Lodge<sup>1</sup>*

*3. Monash university, School of public health and preventive medicine, Melbourne, VIC, Australia.*

**Abstract:** Background/Aim Household exposures may induce lung oxidative stress and increase asthma risk. This risk may be modified by variants of Glutathione S-Transferase (GST) genes. We aimed to determine whether household exposures influenced asthma risk in middle-aged adults and whether this was modified by GST genes. Methods We used data from the Tasmanian Longitudinal Health Study, which followed the whole population of Tasmanian 7 year olds from 1968 until their 6th decade (aged 53 years). Information from 3314 participants about consistent household exposures (heating, cooking, mould, carpets, pets, smoking) and asthma were obtained by questionnaires at ages 45 and 53. GST genes (GSTM1, GSTT1 and GSTP1) were typed on blood samples collected at age 45. Multivariable logistic regression estimated odds ratios (OR) and 95% confidence intervals (CI) for associations between consistent household exposures (over 8 years) and current asthma at 53 years (asthma symptoms or medication in last 12 months) (N=3314) and interactions by GST genotype (N=928). Results Having carpets in bedrooms consistently (over 8 years) was associated with a reduced risk of current asthma at 53 years (OR 0.55, 95%CI 0.34-0.89), compared with no bedroom carpets, after adjusting for baseline asthma. Persistent active smoking was associated with an increased risk of current asthma at age 53 (OR 1.47, 95%CI 1.06, 2.00) compared with never smokers, but there was no association with environmental tobacco smoke, or other household exposures. GST genes were not associated with asthma and did not modify relationships between household exposures and asthma. Conclusions We found evidence that bedroom carpets reduced asthma risk in middle age, whereas active but not passive smoking at home increased asthma risk. GST genes did not modify relationships between household exposures and asthma. The unexpected finding for carpets may be reverse causation, requiring further investigation.

## **P01.2820. A Profile of Exhaled Volatile Organic Compounds Measured Using PTR-TOF-MS for Diagnosis of Chronic Obstructive Pulmonary Disease**

Xu Yifan

*Xu Yifan<sup>1</sup>, Ying Liu<sup>1</sup>, Xi Chen<sup>1</sup>, Xinghua Qiu<sup>1</sup>, Chengli Que<sup>2</sup>, Lina Zhang<sup>3</sup>, Guancong Huang<sup>1</sup>, Qi Wang<sup>1</sup>, Yuan Yao<sup>1</sup>, Wu Chen<sup>1</sup>, Tong Zhu<sup>1</sup>*

*1. SKL-ESPC and BIC-ESAT, College of Environmental Sciences and Engineering, Peking University, Beijing, China.*

*2. Peking University First Hospital, Beijing, China.*

*3. Beijing Xicheng District Shichahai Community Health Center, Beijing, China.*

**Abstract:** Background: Chronic obstructive pulmonary disease (COPD) is one of the leading causes of global death. The diagnosis of COPD clinically relying on pulmonary function tests is invasive for the elders. Method: To develop a non-invasive and efficient diagnosis method for COPD, a panel of 102 subjects, including 44 stable COPD patients and 58 healthy control, were recruited in Beijing, China. The exhaled gas of each subject was collected with Tedlar bags and then analyzed with proton-transfer-reaction time-of-flight mass spectrometry (PTR-TOF-MS). Binary logistic regression model was used to evaluate the associations between exhaled VOCs level and the classification of subjects, modified by smoking status. Results: Among 260 VOCs identified as endogenous VOCs, 16 key VOCs had discriminative values. The performance of classification of COPD patients using the 16 VOCs delineates an area under the curve (AUC) of 0.93 in the Receiver Operating Characteristic (ROC) curve. 10-folds cross validation demonstrated that the discriminative model has a predictive accuracy of 0.909. Among the 16 VOCs, the level of [m/z=34.99, 46.03, 47.05, 69.07, 73.03, 101.10, 169.16, 243.08] were not significantly higher or lower in the subjects with asthma, diabetes mellitus, hyperlipemia, or smoke history, which indicates that the method is specific for COPD diagnosis. Tentative conclusion: In conclusion, several specific exhaled VOCs were screened out for the non-invasive diagnosis of COPD using PTR-TOF-MS, which is promising for clinical uses. The screened VOCs should be further characterized and their metabolic pathways require further research.

## **P01.2830. MnSOD Polymorphism May Modify the Association between Exposure to Dioxin and Diabetes**

Ya Chang

Ya C. Chang<sup>1</sup>, Hui-Tsung Hsu<sup>2</sup>, Bing-Fang Hwang<sup>1</sup>

1. Department of Occupational Safety and Health, China Medical University, Taichung, Taiwan.

2. Department of Health Risk Management, College of Public Health, China Medical University, Taichung, Taiwan.

**Abstract:** Background/Aim: Manganese superoxide dismutase (MnSOD) is an antioxidant, and might play an important role to diabetes (DM) pathogenesis. Dioxin may also cause effects with aryl hydrocarbon receptor (AhR) and induce DM. The interaction between exposure to dioxin and MnSOD gene polymorphism has not been investigated yet. Our study was to assess the joint effects of MnSOD polymorphism and exposure to dioxin on the risk of DM. Methods: A total of 282 individuals were selected from Central Taiwan to conduct a cross-sectional study. We used real-time polymerase chain reaction (RT-PCR) to analyze the four single-nucleotide polymorphisms (SNPs) of MnSOD (rs5746136, rs2855116, rs4880, rs2758346) and performed Haploview v4.1 software to test the MnSOD gene for Hardy-Weinberg equilibrium. The dioxin data were measured by chromatography/mass spectrometry (HRGC/HRMS) and divided dioxins levels into four groups: reference group (<25th), low exposure group (25th to <50th), middle exposure group (50th to <75th) and high exposure group ( $\geq$ 75th). We performed logistic regression models to assess the risk for diabetes and applied Rothman index (s) to estimate interaction in additive scale. Result: After adjusting for confounding, we found that the risk of DM was associated with the low and middle combined exposure group of OCDF(aOR=3.25; 95% CI=1.07-9.81), PCDDs(aOR=5.12; 95% CI=1.46-18.62), 1,2,3,7,8-PeCDD(aOR=4.03; 95% CI=1.18-13.78), 1,2,3,4,7,8-HxCDD(aOR=3.79; 95% CI=3.79-13.37) and OCDD(aOR=4.00; 95% CI=1.42-11.26) as compared with reference group. Additive interactions between SNP (rs2758346) and the specific dioxin (PCDDs: S=1.592; 1,2,3,7,8-PeCDD: S=2.138; 1,2,3,6,7,8-HxCDD: S=1.642) on the risk of diabetes was found. Conclusions: Our study suggests that MnSOD (rs2758346) may modify the association between exposure to specific dioxin (PCDDs, 1,2,3,7,8-PeCDD and 1,2,3,6,7,8-HxCDD) and DM.

**P01.2840. Effects of 3-PBA on Complete Blood Count (CBC) and Liver Enzyme in Human: The Second Korean National Environmental Health Survey (KONEHS)**

Yuming Lee

Yumin Lee<sup>1</sup>, Eun Mi Jung<sup>1</sup>, Eunhee Ha<sup>1</sup>

1. *Occupational and Environmental Medicine, Ewha Womans University College of Medicine, Seoul, Republic of Korea, Seoul, Korea (the Republic of).*

Abstract: Pyrethroid were synthetic analogues insecticides as pyrethrins. They are known to be effective in insects because they are degraded by rapid metabolism in mammals. However, health effects that occur are not clearly known in human. In this study, we evaluated the effect of exposure of low concentrations of insecticide, rather than high concentration exposure, on human health. This study was performed on 5474 adults aged 19 years and older based on the Second Korean National Environmental Health Survey(KoNEHS 2012-2014). We used regression analysis to examine the effects of 3-PBA (phenoxybenzoic acid, as metabolite of pyrethroid) levels in urine on the complete blood count (CBC; white blood cell, red blood cell, hemoglobin, and platelet) and liver enzymes (AST, ALT,  $\Gamma$ -GPT). As clinical laboratory values are different according to sex, they are stratified. Thus, urinary 3-PBA/Cr, liver enzymes were transformed logarithmically due to their skewed distribution. Geometric mean concentrations of urinary 3-PBA were 1.94 $\mu$ g/L/Cr in total, 1.59 $\mu$ g/L/Cr in men, and 2.41 $\mu$ g/L/Cr in female, respectively. Association between log-transformed urinary 3-PBA and liver enzymes were not statistically significant. However, association between log-transformed urinary 3-PBA and RBC and hemoglobin were statistically significant, respectively (adjusted coefficient=-0.018 (0.009),  $p=0.0425$ ; -0.043(0.025)  $p=0.0791$ ). After stratification, there was a negative association between log-transformed urinary 3-PBA and RBC and hemoglobin only for male group (adjusted coefficient=-0.024 (0.035),  $p=0.0385$ ; -0.097(0.011)  $p=0.0064$ ). Low concentrations of pyrethroid exposure showed a statistically significant decrease in RBC and hemoglobin in humans. Liver enzymes, however, tended to increase, although not statistically significant. The results of this study need to educate the public about not being exposed to pesticides, and in order to do so, we must try to find these exposure factors in our living environment.

**P01.2842. Persistent Organochlorine Pollutants: Genetic Variations Associated with DDE and PCB153 Blood Levels among Women in France**

Takiy Eddine Berrandou

*Takiy Eddine Berrandou<sup>1</sup>, Emilie Cordina-Duverger<sup>1</sup>, Claire Mulot<sup>2</sup>, Thérèse Truong<sup>1</sup>, Pascal Guenet<sup>1</sup>*

*1. CESP-INSERM, Paris-Sud University, France. 2. University Paris Descartes, Inserm UMRS 1147 EPIGENETEC, Paris, France.*

**Abstract:** Persistent Organochlorine Pollutants including Dichlorodiphenyltrichloroethane (DDT) and polychlorinated biphenyls (PCBs) are ubiquitous in the environment. Many studies have attempted to link DDT or PCB levels in human tissues to the risk of breast and other cancers. However, little attention has been paid to the genetic determinants of DDT and/or PCBs levels. Our aim was to identify genetic variants modifying blood levels of DDE (the major breakdown product of DDT) and PCB153 measured in a sample of women in France. Blood levels of circulating DDE and PCB153 were measured in 1236 healthy women selected as control subjects in an epidemiological study on breast cancer. We genotyped 474 Single Nucleotide Polymorphisms (SNP) in 54 CYP and GST genes involved in the metabolism of DDT and PCBs. Blood concentrations of DDE and PCB153 were explored in relation to each SNP and to the genetic variation in the genes using the Adaptive Rank Truncated Product method. This approach allows investigating the role of a gene seen as a set of SNPs or of a set of genes in DDE and PCB153 levels, and to gain statistical power as compared to a SNP by SNP approach. P-values were adjusted for multiple testing by False Discovery Rate (FDR) method. Blood levels of DDE and PCB153 were significantly associated with several SNPs located in CYP genes. The top-SNPs were rs8192719 (FDR=3x10<sup>-26</sup>) for DDE and rs7255904 (FDR=0.01) for PCB153, both located in CYP2B6. At the gene level, CYP2B6 was associated with levels of DDE (FDR=2x10<sup>-4</sup>) and PCB153 (FDR=0.01). Genetic variation in the whole gene-set including CYPs and GSTs was significantly associated with blood levels of DDE (p=2x10<sup>-4</sup>) and PCB153 (p=2x10<sup>-4</sup>). These findings show that polymorphisms in genes involved in the metabolism are important determinants of organochlorine compound levels measured in humans, and should be taken into account as possible modifiers of the association between PCB and DDT levels and disease risk in epidemiological studies.

## P01. Risk Assessment and Policy 1

### **P01.2850. The Consumption of Fluoridated Water during the Development of the Rat Modifies the Emotional State**

Jairo Alvarez

*Jairo Alvarez<sup>1</sup>, Mario Flores<sup>2</sup>, María I. Pérez<sup>1</sup>, César Soria<sup>1</sup>*

*1. University of Guadalajara, Guadalajara, Mexico.*

*2. University of Guadalajara, Guadalajara, Mexico.*

**Abstract:** Background/Aim: Access to safe drinking water is essential to health, a basic human right and a component of effective policy for health protection. Fluoride (F) is present ubiquitously in the environment, including surface and groundwater. This compound has therapeutic properties to prevent tooth decay at low concentrations, but some research has demonstrated its toxic effects at several concentrations. Clinical and experimental studies have reported that F induces changes in cerebral morphology and biochemistry that affect emotional processes, such as anxiety and depression. The World Health Organization recommends a F concentration of 1.5 mg/L; in Mexico, the legislation establishes 0.7 mg/L as the maximum limit for drinking water. The aim of this study was to evaluate the effects of F on behavior through the forced swim test (FST) in rats exposed to F in drinking water. Method: Male Wistar rats were exposed orally to F in drinking water at concentrations of 0.7, 1.5, 5 and 10 mg/L since gestation until 90 days after parturition. Two control (C1 and C2) groups were performed, C1 with distilled water and C2 with distilled water and fluoxetine at 1 mg/kg during the last 10 days. After exposure, FST and open field test were carried out to determine the depressive-like behavior and to exclude locomotor impairment, respectively. Results: F exposure at these doses changes the variables evaluated in FST, e.g. immobility, but do not alter locomotive capacities. Fluoxetine administration in C2 group decreased immobility in comparison to C1 group and without changes on locomotor activities. Conclusions: Results shows that exposure to F during development can yield to a depressive-like behavior in rats, suggesting that high intake of F must be prevented to avoid harmful effects at adulthood.

**P01.2860. Children's Lead Exposure from Consumption of Backyard Chicken Eggs: Health Risks from a Non-Traditional Source**

Komal Basra

*Komal Basra<sup>1</sup>, Marieke Rosenbaum<sup>2</sup>, Alyssa McDonagh<sup>2</sup>, Catherine Ressijac<sup>2</sup>, Thomas Ireland<sup>3</sup>, Donna Vorhees<sup>1</sup>, Wendy Heiger-Bernays<sup>1</sup>, Jessica Leibler<sup>1</sup>*

- 3. Department of Earth and Environment, Boston University College of Arts and Sciences, Boston, MA, United States.*

Abstract: Backyard chicken (BYC) ownership is increasingly popular in the United States, especially in urban areas, largely motivated by a desire for fresh, non-commercial eggs and engaging children in agriculture. The role of BYC egg consumption as a pathway for exposure to environmental contaminants, particularly child exposure to lead, remains largely unstudied. A limited number of studies in the US and Europe document lead in BYC eggs and report levels that exceed those in commercial eggs, but children's health risk from BYC eggs has not been determined. To characterize lead exposure and health risk among children consuming BYC eggs, we conducted a cross-sectional study of BYC owners in Greater Boston, MA, US (n=51). From these households, we collected 201 egg samples and analyzed them for lead concentration using inductively coupled plasma mass spectrometry (ICP-MS). Lead was detected in 96% of the egg samples. Concentrations ranged from below the detection limit ( $2.0 \times 10^{-6}$ ) to 1.798  $\mu\text{g/g}$  with median and mean concentrations of 0.022 and 0.098 (SD: 0.204)  $\mu\text{g/g}$ , respectively. We incorporated egg lead concentration data along with egg consumption rates for children living in the households into the USEPA's Integrated Exposure Uptake Biokinetic Model to predict child blood lead levels (BLLs). We then compared BLLs to the California EPA (CalEPA) child-specific reference dose (chRD) of 1.0  $\mu\text{gPb/dL}$  blood. For children less than 7 years old who frequently eat eggs (about 4 medium eggs/week) with a 95th percentile lead concentration of 0.324  $\mu\text{g Pb/g}$  egg, the incremental change in blood lead was predicted to be 0.9 to 1.5  $\mu\text{g/dL}$ . The upper end of this range exceeds the CalEPA chRD, which is intended to protect against increased risk of neurological deficit due to lead exposure. Our results reflect the highest detected lead concentrations in BYC eggs reported to date. Frequently consuming BYC eggs with high egg lead concentrations may pose health risks to children.

## **P01.2870. Clinical Indices and Fatal Cases in Hospitalized H7N9 Patients**

Ying Chen

*Ying Chen<sup>1</sup>, Wenbiao Hu<sup>2</sup>, Jiahai Lu<sup>1</sup>*

*1. School of Public Health, Sun Yat-sen University, Guangzhou, Guangdong, China.*

*2. School of Public Health & Social Work, Queensland University of Technology, Brisbane, QLD, Australia.*

**Abstract:** Background/Aim: H7N9 has lasted for over five years in China, resulted in more than 1500 cases with a fatality rate of 40.5%. This research aimed to identify the key clinical indices and estimated the fatality risk of infected H7N9 patients admitted to hospital. Methods: We performed a retrospective epidemiological investigation to collect laboratory - confirmed H7N9 viral infected cases from 2013 to 2015 in Guangdong province, China. Data with clinical outcomes and biochemical indices were collected after patients and hospitals permission. Multivariable logistic regression model and classification tree model were used to evaluate the risk factors of H7N9 death. The receiver operating characteristic curve (ROC) and survival analysis were used to compare survival and death distribution and difference. Results: The results indicated that body temperature (BT) average (Odds Ratio (OR) = 3.612, 95% Confidence Interval (CI) = 1.914-6.815), white blood cell (WBC) average (OR = 1.212, 95%CI = 1.092-1.346), WBC maximum (OR = 1.095, 95%CI = 1.043-1.149), hemoglobin minimum (OR = 0.981, 95%CI = 0.965-0.996), platelet average (OR = 0.990, 95%CI = 0.986-0.995), lymphocyte average (OR = 0.230, 95%CI = 0.064-0.831) were identified as the independent risk factor for mortality with H7N9 after adjusting the confounders (underlying disease, age and sex). Moreover, WBC average, WBC maximum and BT average were the most reliable indices for predicting mortality with high sensitivity and specificity. There was an 80.0% chance for a death of H7N9 if BT was over 38.1°C, 67.4% chance if WBC average over 9.5 ( $10^9/L$ ) and 86.4% chance if WBC maximum over 23.1 ( $10^9/L$ ). Conclusions: We screened a series of clinical variables through rigorous statistical methods to provide a reference for the treatment and survival prediction of H7N9 cases.

**P01.2880. The Role of the Gut Microbiome on Mercury Toxicology: Protein-Rich Diet Alters Gut Microbiota Composition and Increases Methylmercury Demethylation**

Galen Guo

*Galen Guo<sup>1</sup>, Emmanuel Yumvihoze<sup>1</sup>, Laurie Chan<sup>1</sup>, Alexandre J. Poulain<sup>1</sup>*

*1. Biology, University of Ottawa, Ottawa, ON, Canada.*

Abstract: Methylmercury (MeHg) exposure is a global health concern particularly among coastal populations that rely on fish and marine mammals for sustenance. It has been shown that diet can modulate the MeHg kinetics and body burden. The gut microbiome has been identified as a major factor affecting contaminant metabolism, but little is known about the role of gut microbiota on mercury transformations. The objective of this study was to examine the effects of diet on the human gut microbiome and its subsequent effect on MeHg metabolism. Using a series of batch experiments, we evaluated the effects of a changing nutritional component of the diet (by altering relative abundances of carbohydrate or protein) in the gut microbial community structure of two individuals. We measured mercury methylation and demethylation rates using a stable isotope tracer and conducted high throughput sequencing of the 16S rRNA metagenomic analysis to determine the microbial community structure. We observed >90% decrease in initial MeHg concentration in protein-rich diet mixed with the fecal slurry of individual A. Moreover, two microbial taxa were significantly increased from non-detectable to a total of 20% in relative proportion. Individual B gut microbiota did not exhibit similar results. A mixture of different ratios of gut microbiota of individual A and B showed similar demethylation rate as in individual A indicating that the phenotype can be conserved. Our results show that the gut microbiome of some individuals contains microbiota that can be promoted by a protein-rich diet and can increase demethylation of MeHg. The mechanism of the demethylation of MeHg needs to be characterized.

**P01.2890. Association between Private Drinking Water Wells and the Incidence of Campylobacteriosis in Maryland: An Ecological Analysis Using Data from the Foodborne Diseases Active Surveillance Network (FoodNet)**

Rianna Murray

*Rianna T. Murray<sup>1</sup>, Sacoby M. Wilson<sup>1</sup>, Raul Cruz-Cano<sup>1</sup>, Amy R. Sapkota<sup>1</sup>*

*1. School of Public Health , University of Maryland, College Park, College Park, MD, United States.*

**Abstract:** Background: Campylobacter is a leading cause of foodborne illness in the United States. Campylobacter infections have most often been associated with food-related risk factors, but recent studies have identified environmental risk factors for campylobacteriosis, including contact with livestock and consumption of contaminated water. No previous studies have evaluated the association between private wells and campylobacteriosis rates in Maryland. Given that the Safe Drinking Water Act does not regulate the water quality of private wells, these could be an important non-foodborne transmission pathway for Campylobacter. Objective: We examined the zip code-level association between the number of households in Maryland that rely on drinking water from private wells and the incidence of campylobacteriosis. Methods: Data on culture-confirmed cases of Campylobacter infection in Maryland between 2007-2016 were linked by zip code with data from the Maryland well permits registry, the 2010 US Census and the USDA agricultural census. Campylobacteriosis incidence rates were calculated by zip code and a multivariate, negative binomial regression model was used to evaluate the association between private wells and the incidence of campylobacteriosis. Results: From 2007-2016, a total of 5,746 cases of campylobacteriosis were reported in Maryland, and annual incidence rates ranged from 6.65 to 11.59 per 100,000 people. A significant positive association was detected between number of private wells in a zip code and the risk of campylobacteriosis (Incidence rate ratio =1.033; 95% CI =1.0005, 1.0666). Similarly, the presence of broiler chicken operations in zip codes was also associated with campylobacteriosis incidence (IRR=1.286; 95% CI=1.0898, 1.5195). Conclusion: This project provides evidence that drinking water source may be an important risk factor for campylobacteriosis in the State of Maryland.

## **P01.2900. Health Impact Assessment and the Relationship with the Environment: An Integrating Review**

Simone Nothaft

*Simone C. Nothaft<sup>1</sup>, Maria A. Busato<sup>1</sup>*

*1. Programa de Pós-Graduação em Ciências da Saúde, Unochapecó, São Carlos, Brazil.*

**Abstract:** Objectives To identify the approach of scientific literature on Health Impact Assessment related to the environmental theme. Method Integrative literature review with search for studies with the terms health impact assessment and environment in the Portal of Periodicals of the Coordination of Improvement of Higher Level Personnel following the steps of the protocol elaboration and external validation, data collection, selection and critical evaluation of the studies, analysis of data and results that were organized into thematic categories. Results 38 studies were included, and the period with the highest number of publications was between 2012 and 2014, with studies developed mainly in Europe and North America. The categories that resulted were the practice of Health Impact Assessment, Health Impact Assessment and Urban Planning, Environmental Impact Assessment and Health Impact Assessment and Environment and Health. Conclusions The Health Impact Assessment is an important decision-making process, evidencing the need to expand its scientific production, discussions and results on the evaluation of health impacts of enterprises, public policies or programs resulting from the process of economic development. There is a movement for the inclusion of health in all policies, including in defense of the institutionalization of the integration between health impact assessment and environmental impact assessment, since it already has its consolidated legal base.

## **P01.2910. Alternatives Assessments for Hazardous Chemicals in Children's Consumer Products: Can Predictive Toxicology Tools Help?**

Marissa Smith

*Marissa N. Smith<sup>1</sup>, Elaine Cohen Hubal<sup>2</sup>, Faustman Elaine<sup>1</sup>*

- 1. Environmental and Occupational Health, University of Washington, Seattle, WA, United States.*
- 2. Chemical Safety for Sustainability Research, US EPA, Research Triangle Park, NC, United States.*

**Abstract:** Exposure to toxic chemicals in consumer products can have lasting impacts on children's health due to their increased vulnerability during sensitive periods of development. Regulation and reporting requirements have increased demand for safer alternatives. This project examines how predictive toxicology tools can fill data gaps in alternatives assessments for hazardous chemicals found in children's consumer products. Data available from European Chemical Agency's (ECHA) Endocrine Disruptor Substances of Concern classification was compared with predictive toxicology tools that rely on in silico and in vitro data: The toxicological prioritization index (ToxPi), calculated based on information in the US EPA's ToxCast Database; and exposure rankings developed in the high throughput exposure screening program., ExpoCast. Three chemical groups were considered: phthalates, parabens and bisphenols. Only one out of the 24 alternative chemicals had data available through ECHA, yet in vitro data from ToxCast was available for 83% of alternative chemicals and animal in vivo data from the Comptox Chemistry Dashboard was available for 66% of alternative chemicals. The No Observable Adverse Effects Levels derived from the in vivo studies were higher for alternative than conventional chemicals, suggesting the alternatives may be less toxic. ToxPi scores, however, showed little difference between conventional and alternative chemicals. ExpoCast rankings were available for 20 of the 24 alternative chemicals. The rankings indicated that conventional chemicals have higher predicted exposure than alternatives. The results from this case study suggest that predictive toxicology tools can help fill data gaps when existing classifications are incomplete. This project is supported by the US EPA (FP-91779601-0, RD 83573801, RD 83451401) and the US NIEHS (5P01ES009601). The views expressed in this paper are those of the authors and do not necessarily reflect the views of the US EPA.

## **P01.2930. Arsenic Bioconcentration in Freshwater Fish Species in a Pristine Lake in Yellowknife, NT**

Claudia Tanamal

*Claudia Tanamal<sup>1</sup>, Jules M. Blais<sup>1</sup>, Laurie Chan<sup>1</sup>*

*1. University of Ottawa, Ottawa, ON, Canada.*

Abstract: Yellowknife hosts one of the largest gold mining industries in Canada, including the renowned Giant Mine actively operating from 1948 to 2004, The mining operation in Giant Mine released enormous amounts of arsenic trioxide dust to the environment from the burning of arsenopyrite ores necessary to extract gold. Studies have revealed up to 100-fold increases in the concentration of arsenic in the surface water of lakes located within a 5-km radius of the mine. We summarized different factors from previous studies that contribute to the high arsenic levels found in lakes in Yellowknife: distance from the Giant Mine, prevailing wind direction to the Northwest, and the size of the lake. In this study, Small Lake was chosen as a pristine lake; a medium-sized lake located 27-km East of the mine and away from the city centre. Small Lake has the background concentration of arsenic of 1.4 µg/L in its surface water, unaffected by the historical activities from the Giant Mine. This background level of arsenic is expected from the slow natural weathering process of the bedrock geology. We collected two most common freshwater fish species in lakes in Yellowknife: Adult Lake Whitefish (*Coregonus clupeaformis*) (n=8) and adult Northern Pike (*Esox lucius*) (n=8). Total arsenic concentration in the tissues was measured using ICP-MS method following FDA standard. Results show arsenic concentrations of  $0.567 \pm 0.216$  mg/kg dry weight in the muscle tissue of Lake Whitefish and  $0.458 \pm 0.115$  mg/kg dry weight in the muscle of Northern Pike. Although the Northern Pike species in this study is in a higher trophic position than the Lake Whitefish species, no significant difference in the arsenic concentration is observed in the muscle tissues ( $p > 0.05$ ). The results of this study serve as reference data for fish arsenic monitoring programs and risk assessment projects in Yellowknife.

## **P01.2950. Incorporating Unique Exposure Pathways of the Diné People into a Community-Based Probabilistic Risk Assessment Following the Gold King Mine Spill**

Yoshira Van Horne

Abstract: On August 5th 2015, the Gold King Mine Spill released 3 million gallons of acid mine drainage-containing arsenic (As) and lead (Pb) into a tributary of the San Juan River, which flows through the Navajo Nation. The Diné (Navajo) rely on this River and use it for a variety of purposes lending to unique exposure pathways. We administered questionnaires in three Navajo communities in collaboration with the Navajo Nation Community Health Representatives to obtain frequency and duration data on 42 activities. These activities were utilized to conduct a community-based probabilistic risk assessment from exposure to As and Pb: 1) before the Spill, 2) during peak of the Spill, and 3) one year after the Spill. To estimate exposure to As and Pb before the Spill, we utilized historical surface water (n=32) and sediment data (n=20) obtained from the USGS. Estimation of exposure to As during peak Spill incorporated As and Pb surface water (n= 92) and sediment (n=75) concentrations obtained from U.S. EPA publically available data. To estimate exposure to As and Pb one year after the Spill, we collected surface water (n=101) and sediment samples (n=127) in these three Navajo communities within one year after the Spill. Surface water concentrations of As and Pb were significantly different between periods (p-value <0.0001), with concentrations highest during the peak of the Spill, followed by pre-Spill and post-Spill levels. Sediment concentrations were significantly different (p-value <0.0001), but with concentrations highest before the Spill, followed by peak-Spill, and post-Spill. The risk assessment for arsenic and lead through these unique water/sediment pathways indicate both potential chronic and carcinogenic risks to the local Diné community. This research provides the first documentation of unique exposure pathways of the Diné people and raise the need to understand and document unique exposure pathways of indigenous communities with subsistence and land-based livelihoods.

## **P01.2960. The Importance of Developing Exposure Factors Handbook in Nigeria**

Nathaniel Wambebe

*Nathaniel M. Wambebe<sup>1</sup>, Xiaoli Duan<sup>1</sup>*

*1. Environmental Exposure and Health Risk Assessment Center, School of Energy and Environmental Engineering, University of Science and Technology, Beijing, P.R.China, Beijing, China.*

Abstract: As environmental conditions continue to change and deteriorate, the residents in African Countries such as Nigeria have become increasingly threatened by continuous exposure to contaminants in gradient concentrations but with little or no adherence to environmental regulations by the government. Nigeria is also facing with great increase in number of potential health risk associated with environmental contamination with the UN projection on increase in population. It is now imperative that the government, regulatory bodies, scientist, industrialist and general public are aware of the dangers that contaminated soil, water, air, foodstuffs, and consumer products pose to humans and the ecosystem and how to manage these risks to protect human and ecological health. However, as of the time of writing the paper, no Environmental regulatory agency in Nigeria has a complied data or handbook will serve as a national index for demonstrating the physiological, food ingestion, and behavioral characteristics of the Nigerian people so as to provide basic information for health risk assessment and risk management. Since African people have unique exposure patterns and specific time-activity owing to the geological, social and economic difference, the existing Exposure Factors Handbooks in North American, Europe and other countries as USA, Canada and China cannot be used in evaluating the risks of Nigerian population. It is thus imperative to develop Exposure Factor Handbook to provide basic information for health risk assessment and to enlighten and sensitize Nigerians on the risks of environmental and health hazards. The paper highlights the significance of exposure factor handbook, the need for Nigeria to join list of countries with exposure factor handbook.

## **P01.2970. Propensity Score Matching in Environmental Epidemiology: A Systematic Review and Reporting Recommendations**

Mary Willis

*Mary Willis<sup>1</sup>, Dede Long<sup>2</sup>, Devin Sonne<sup>3</sup>, Molly Kile<sup>1</sup>, Elaine Hill<sup>3</sup>, Perry Hystad<sup>1</sup>*

- 2. College of Agricultural Sciences, Oregon State University, Corvallis, OR, United States.*
- 3. School of Medicine and Dentistry, University of Rochester, Rochester, NY, United States.*

**Abstract:** Background: Propensity score matching (PSM) is a statistical technique from econometrics to simulate a randomized trial in observational data. This method allows researchers to create a sample where exposed and unexposed groups probabilistically differ only on exposure status. Although PSM has recently increased in popularity, there is little guidance for environmental researchers on applying this technique and transparently reporting the results. Methods: We conduct a systematic literature review via PubMed and Web of Science to find epidemiological articles that used PSM for an environmental exposure with a chronic disease outcome. Using established reporting standards from econometrics, we assess PSM methods used and transparency of reporting for each article. We then demonstrate the need for sensitivity analyses of PSM using traffic-related air pollution and term birth weight to highlight unique PSM challenges in environmental settings. Finally, we create a reporting checklist for researchers who want to use PSM in their own work. Results: We found 37 studies that met our search criteria. Little consistency exists regarding what is reported and how PSM is conducted. Our example using traffic-related air pollution and term birth weight demonstrates that PSM results are sensitive to matching criteria and statistical specification. Recommendations: We propose that studies report three specific metrics to demonstrate that effective PSM occurred: 1) A figure showing the propensity score distribution of units between exposed and unexposed groups; 2) A table exhibiting covariate distributions before and after matching with appropriate bias calculations; and 3) Sensitivity analyses of final PSM results using different matching schema to demonstrate robustness. Conclusion: PSM has potential to be a powerful tool for environmental epidemiology, but transparent reporting methods and robustness checks are needed to ensure that PSM is being correctly applied.

## **P01.2980. Phthalate and Organophosphate Plasticizers in Nail Polish: Evaluation of Ingredients and Labels**

Anna Young

*Anna Young<sup>1</sup>, Joseph G. Allen<sup>1</sup>, Un-Jung Kim<sup>2</sup>, Stephanie Seller<sup>3</sup>, Thomas F. Webster<sup>4</sup>, Kurunthachalam Kannan<sup>2</sup>, Diana M. Ceballos<sup>1</sup>*

- 1. Harvard T.H. Chan School of Public Health, Boston, MA, United States.*
- 2. Wadsworth Center, New York State Department of Health, Albany, NY, United States.*
- 3. Boston Public Health Commission, Boston, MA, United States.*
- 4. Boston University School of Public Health, Boston, MA, United States.*

**Abstract:** In the last decade, nail polish manufacturers largely phased out use of the three widely publicized "toxic trio" chemicals, including the plasticizer dibutyl phthalate (DnBP). These "3-Free" nail polishes may instead contain the plasticizer triphenyl phosphate (TPHP), a possible endocrine disruptor. Nail polish users and majority-Vietnamese nail salon workers in the U.S. are vulnerable populations potentially exposed to these plasticizers. To better understand plasticizer ingredient substitution, this study aimed to 1) identify plasticizer-related nail polish product labels through online searches, and 2) measure levels of 12 phthalate and 10 organophosphate plasticizers in 40 nail polishes. The 40 samples comprised different colors from 12 brands selected based on popularity and label variety. Summary statistics and Wilcoxon rank sum tests were calculated for plasticizer levels, substituting half the detection limit for non-detect values. We identified 11 n-Free labels ranging from 3-Free to 13-Free that reported the exclusion of n ingredients, with 5-Free the most common. The label definitions varied by brand, with 6 different definitions of 10-Free. Over half of nail polishes 6-Free or higher advertised the exclusion of TPHP. For the 40 samples, concentrations reached up to 7940 µg/g for organophosphates (TPHP) and 331 µg/g for phthalates (bis[2-ethylhexyl] phthalate [DEHP]). All DnBP levels were below 0.5 µg/g. TPHP levels were statistically lower in the 28 newer generation 5- to 13-Free samples compared to the 12 conventional or 3-Free samples (median 0.001 vs. 3730 µg/g,  $p < 0.001$ ). DEHP levels were statistically higher for the 16 nail polishes without detection of TPHP than the 24 with detection (68.5 vs. 1.51 µg/g,  $p < 0.05$ ). In conclusion, the evolving nail polish labels are varied and diversely defined. Our results suggest that DnBP and TPHP are now excluded or reduced from many polishes, but some concerns about plasticizer ingredients remain.

## **P01.2990. Refine Health Benefit Prior-Evaluation of Emergency Response Measures Under Heavy Pollution Weather**

Qi Zhou

*Qi Zhou<sup>1</sup>, Miaomiao Liu<sup>1</sup>, Jun Bi<sup>1</sup>*

*1. School of the Environment, Nanjing University, Nanjing, Jiangsu, China.*

**Abstract:** In a realistic scenario people move and get exposed to different microenvironment (ME) with varying PM<sub>2.5</sub> levels. While the traditional health impacts assessment directly overlaid static population with ambient PM<sub>2.5</sub> concentrations, without considering diverse individual Activity Patterns (AP), bringing great uncertainties in PM<sub>2.5</sub>-related mortality burden assessment. So to refine exposure assessment considering AP, and applied it to the assessment of the Emergency Response Measures (ERMs) for heavy pollution weather. We carried out Activity Pattern Survey (APS) to investigate the time spent in certain ME and on certain activity types. Based on population density maps and APS data, the Random Forest Model and Agent Based Model were used to establish the rules of individual activity decisions and simulate the Population Distribution Embedded with AP (PD-AP), respectively. Then, indoor/outdoor PM<sub>2.5</sub> concentration ratios of ME were summarized through literature research and were applied to calculate the ME PM<sub>2.5</sub> levels by modifying the ambient PM<sub>2.5</sub> levels. Finally, based on PD-AP, ME PM<sub>2.5</sub> levels, and doses-response relationship, we used the Relative Risk Model to evaluate PM<sub>2.5</sub> attributed deaths under 8 ERMs. And we also compared results under PD-AP, Uniform Population Distribution (UPD) and Static Population Distribution (SPD), to figure out the importance of improving simulation ability of the real distribution of population. The traditional UDP and SDP methods overestimated PM<sub>2.5</sub> attributed deaths, and this overestimation was far greater than changes of attributed deaths caused by choosing different ERMs. Therefore, it is of great importance of considering diversities of population AP for improving accuracy of PM<sub>2.5</sub> exposures assessment. Among 8 ERMs, Intensified Control Scenario in Jiangsu should be selected to deal with heavy pollution weather for its maneuverability and good performance of reducing attributed deaths especially in highly polluted areas.

## **P01.3000. Affecting Factors of Exposure to Influential Factors Assessment for Humidifier Disinfectant Victims in Korea**

Hyeon-Su Ryu

*Hyeon-Su Ryu<sup>1</sup>, Jinhyeon Park<sup>1</sup>, Pan-Gyi Kim<sup>2</sup>, Sunshin Kim<sup>3</sup>, Wonho Yang<sup>1</sup>*

- 1. Occupational Health, Daegu Catholic University, Gyeongsan, Gyeongbuk, Korea (the Republic of).*
- 2. Industrial Environmental Health, Yong In University, Gyeonggi-do, Korea (the Republic of).*
- 3. Environmental Health Center, Soonchunhyang University Gumi Hospital, Gumi, Korea (the Republic of).*

Abstract: Health adverse effect such as lung disease caused by chemical substances (PHMG, PGH, CMIT/MIT) used in humidifier disinfectants occurred in Korea. 6,005 of requests have been registered up to March 30, 2018 including 1,320 of the dead since 2011 when environment exposure survey has begun. Ministry of Environment of Korea (ME) has conducted comprehensive judgment including medical and environment exposure assessment for victims to evaluate lung disease and causal relationship by exposure to humidifier disinfectant, and organized the Expert Judgment Committee, and conducted a comprehensive judgment. Relationships between exposure characteristics such as ingredient of product, use amount, and use characteristics and health effects were conducted for 2,203 victims from 2011 to 2017 by using of exposure questionnaire. The categories that recorded in survey such as daily using time, cumulative time, using time during sleep, distance from respiratory organ, spraying direction, concentration in the air, exposure level of humidifier disinfectants were scored and exposure levels were graded. We assessed the characterization of exposure to humidifier disinfectants for victims using questionnaire survey, and classified the exposure levels into 5 grades such as definite, probable, possible, indeterminate and unlikely. As victim register order increase, the rate of victims of grade 'definite' decrease. There were differences between scored exposure grades and final judgements. The statistical test shows differences in results of comprehensive judgment and environment exposure assessment. It can be explained by the records of the questionnaire on past exposures may be uncertain due to recall bias or psychological effects. If the various health effects data of the humidifier disinfectant victims are analyzed, the users with similar conditions of the humidifier usage characteristics might be grouped to inspect the health effect based on the exposure assessment results.

## **P01.3010. Quantifying Environmental Costs for Sustainable Pavement Management**

Filzah Nasir

*Filzah Nasir<sup>1</sup>, Rebecca Saari<sup>1</sup>, Susan Tighe<sup>1</sup>*

*1. Department of Civil and Environmental Engineering, University of Waterloo, Waterloo, ON, Canada.*

**Abstract:** We quantify the effect of Ontario's provincial transportation infrastructure decisions on multipollutant exposures, impacts, and life-cycle costs. A variety of evidence shows that roadway construction and maintenance affect human health and climate change via emissions of air pollutants and greenhouse gases. With recent policy shifts, provincial transportation decision-makers are focused on the role of roadway design and maintenance on these environmental exposures; however, they lack appropriate tools to incorporate them into decisions. Here, we present a decision-making tool that quantifies the health, environmental, and economic impacts of construction, maintenance, and rehabilitation of roads and highways. We examine various pavement design and management approaches, including standard practices, and innovations to processes and materials. We estimate multipollutant emissions, including (CO<sub>2</sub>, NO<sub>x</sub>, SO<sub>2</sub>, PM<sub>2.5</sub>, CO). We review literature that connects these exposures to health and economic impacts directly through marginal damage estimates. Current literature estimates for the cost of emitting a single metric tonne of fine particulate matter range between \$600 and \$50,000 (2010 CAD) depending on the impacts considered and the cost measures used. Preliminary findings for environmental costs of emissions from new-construction of a double-lane, one-kilometre road range between \$300 to \$50,00 for asphalt roads and \$3000 to \$400,00 (2010 CAD) for concrete roads. In this research, we expand on these findings and quantify contributions of uncertainty from exposures, exposure-response, and economic impacts. These findings allow infrastructure managers to account for health-related impacts of environmental exposures, including air pollutants and greenhouse gases, and thus to design more sustainable solutions.

## **P01.3011. Comparisons of Prevalence and Determinants of COPD between Northern and Southern China**

Ning Wang

*Ning Wang<sup>1</sup>, Wenbiao Hu<sup>1</sup>*

*1. Queensland University of Technology, Brisbane, QLD, Australia.*

**Abstract:** Under-diagnosis of chronic obstructive pulmonary disease (COPD) exists extensively due to the absence of the symptom in early stage. Associated social and environmental factors could be utilized to predict the risk of COPD for the early detection. Although COPD prevalence presented significant geographic variations indicating the possible influence of climate and socio-ecological determinants, little research has been done to explore the relative importance of these determinants among different geographic areas. This study aims to identify the relative importance of the determinants and assess their difference between northern and southern China. Data were collected from the nationwide COPD survey which enrolled 66752 adults from 125 counties over 31 provinces in China. All the participants completed a questionnaire and spirometry. Multiple logistic regression model showed that COPD prevalence in southern China was significantly lower than that in northern China (Odd Ratio: 0.8; 95% confidential interval: 0.8-0.9) after adjusting for social and environmental factors. The classification and regression tree (CART) model showed that the most important determinant for COPD was cigarette smoking followed by age ( $\geq 60$  years), and then asthma history in the north, whereas the most important determinant in the south was age ( $\geq 61$  years) followed by cigarette smoking, and then dyspnea. In the north, for participants with the highest risk, the prevalence of COPD (64.0%) was 4.8 times that of the general population (13.3%). In comparison, the prevalence of participants with the highest risk (57.2%) was 4.1 times that of the general population (14.0%) in the south. The determinants for COPD prevalence, their relative importance and the threshold varied between north and south. These results should be used in the primary care in the north and south to assist in early detection of COPD. Further research is needed to explore the ranking of determinants in different climate zones.

## P01. Occupational Issues 1

### **P01.3020. Biomarker Based Occupational Exposome**

Vy Nguyen

*Vy K. Nguyen<sup>1</sup>, Justin Colacino<sup>2</sup>, Olivier Jolliet<sup>2</sup>*

*1. Department of Computational Medicines & Bioinformatics, University of Michigan, Ann Arbor, MI, United States.*

*2. Environmental Health Sciences, University of Michigan, Ann Arbor, MI, United States.*

Abstract: Occupational exposures are thought to be responsible for over 370,000 premature deaths each year. Thus, the precise quantification of occupational exposure is necessary to consider in understanding an individual's exposome, the entirety of chemical exposures in a lifetime. Using the National Health and Nutrition Examination Survey (NHANES) of 220 chemical biomarker concentrations measured in 52,355 participants, we implemented an untargeted approach to systematically contrast occupational exposure differences between blue-collar and white-collar workers, which were defined based on participants' job descriptions. We conducted a series of multiple regression models with chemical biomarker levels as the outcome variable and blue-versus-white-collar categories as the main predictor while adjusting for age, race, gender, smoking, and poverty-income ratio. Cotinine, a biomarker of smoking, is of the highest concentrations in blue-collar workers in industry (295% higher compared to white collar workers) and in blue-collar workers in non-industrial settings (101% higher compared to white collar workers). Industrial blue collar workers have on average more than 27% higher levels of 3-fluoranthene, lead, and pentachlorophenol compared to white collar workers, and non-industrial blue collar workers have on average more than 20% higher levels of pesticides such as p,p'-DDT, Beta-Hexachlorocyclohexane, and DEET acid compared to white collar workers. Compared to industrial blue-collar workers, white collar workers have on average more than 15% higher levels of personal care product related chemicals such as BP-3, Triclosan, and Ethyl paraben. Systematically studying the NHANES chemical biomarkers and occupational datasets by implementing an untargeted approach enables the identification of expected and unexpected exposure differences by job categories. These findings can be utilized to prioritize chemicals and workers for toxicological evaluation or health interventions.

## **P01.3030. The Impact of Heatwaves on Workers' Health and Safety in Australia: A Multi-City Study**

Blesson Varghese

*Blesson M. Varghese<sup>1</sup>, Alana Hansen<sup>1</sup>, Peng Bi<sup>1</sup>, Dino L. Pisaniello<sup>1</sup>*

*1. Public Health, The University of Adelaide, ADELAIDE, SA, Australia.*

**Abstract:** Heatwaves are predicted to increase in frequency, intensity and duration with climate change, and outdoor workers will be particularly vulnerable. This study examined the relationship between heatwave severity and work-related injuries to better define impacts in Australia and identify workers at highest risk. Workers' compensation claims lodged in Brisbane, Melbourne and Perth were obtained for the years 2006-2016. Heatwaves were defined using the Excess Heat Factor, a normalised metric to measure heatwave severity across different climatic regions. Associations between heatwave severity categories (low, moderate and high) and workers' compensation claims stratified by demographic and injury characteristics were estimated using a time-stratified case-crossover models. Non-uniform impacts were observed in subtropical (Brisbane) and temperate cities (Melbourne and Perth). In Brisbane, there was a significant increase in compensation claims during moderate (RR 1.11; 95%CI 1.04-1.19) and high-severity heatwaves (RR 1.24; 95%CI 1.01-1.52). Vulnerable groups included: males, middle-aged and older workers, experienced workers, those in regulated indoor environments and those employed in medium and heavy strength occupations. In Melbourne, moderate-severity heatwaves were associated with an increase in minor injury claims ( $\leq 1$  week of time-loss, RR 1.18; 95%CI 1.02-1.37), while total claims declined during high-severity heatwaves. Young workers, those in unregulated indoor environments and outdoors had elevated risk during heatwaves. In Perth, moderate and high-severity heatwaves were associated with a decline in total claims (RR 0.91; 95%CI 0.85-0.98 and RR 0.86; 95%CI 0.81-1.13). These findings show that heatwaves are associated with increased occupational injuries for both indoor and outdoor workers. However, impacts can vary across cities in different climatic regions, suggesting that region-specific injury prevention interventions may be appropriate during heatwaves.

## **P01.3040. Night Shift Work and Placental Methylation in the Rhode Island Child Health Study (RICHS)**

Danielle Clarkson-Townsend

*Danielle Clarkson-Townsend<sup>1</sup>, Todd M. Everson<sup>1</sup>, Maya Deyssenroth<sup>2</sup>, Amber Burt<sup>1</sup>, Karen Hermetz<sup>1</sup>, Ke Hao<sup>3</sup>, Jia Chen<sup>2</sup>, Carmen J. Marsit<sup>1</sup>*

*1. Environmental Health , Emory University, Atlanta, GA, United States.*

*2. Environmental Medicine and Public Health, Icahn School of Medicine at Mount Sinai, New York, NY, United States.*

*3. Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY, United States.*

**Abstract:** **ABSTRACT** Background: The circadian clock produces cycles of rhythmic biological activity, but disruption of the circadian clock can impact health. Rationale: Exposures that cause circadian disruption, such as night shift work or light at night exposure, are incredibly common, yet little is known about how they impact in utero development. Methods: We investigated whether placental methylation (measured with Illumina 450k array) differed between non-night shift workers (n=184) and night shift workers (n=53) in the Rhode Island Child Health Study (RICHS). We used robust linear modeling to conduct an epigenome-wide association study of night shift work, including covariates for putative cell mixture, maternal age, prepregnancy smoking, infant sex, and maternal adversity. Results: Night shift workers tended to have higher BMI and gestational diabetes compared to non-night shift workers. 10 CpG sites showed differential methylation in night shift workers after Bonferroni adjustment for multiple comparisons ( $p < 0.05$ ). The CpG sites with the most hypomethylation were within NAV1, MXRA8, GABRG1, PRDM16, WNT5A, and FOXG1, while CpG sites with the most hypermethylation were within TDO2, ADAMTSL3, DLX2, and SERPINA1 ( $q < 0.10$ ). PER1 was the only core circadian clock gene demonstrating differential methylation. An analysis of differentially methylated regions (DMRs) indicated DMRs in the NAV1, PURA, C6orf47, and GNAS genes ( $q < 0.10$ ). KEGG pathway and GO-term analysis indicated GO-terms related to cell-cell adhesion. Conclusion: Altered placental methylation, particularly within the neuron navigator 1 (NAV1) gene, was associated with night shift work. Nav1 displayed rhythmicity in mouse SCN tissue, so it may play a role in the circadian clock. Circadian disruption may be an important developmental exposure and future studies should evaluate the impact of shift work on fetal development. Further research should also evaluate shift work as a risk factor for gestational diabetes.

## **P01.3050. Outsourcing Informal Home Workers in Jewelry and Fashion Jewelry Production Present High Prevalence of Preterm Birth**

Flávia Vieira

*Flávia B. Vieira<sup>1</sup>, Ana Paula Sacone da Silva Ferreira<sup>1</sup>, Ana Paula Sayuri Sato<sup>2</sup>, Nilson A. Assuncao<sup>3</sup>, Kelly Polido Kaneshiro Olympio<sup>1</sup>*

*1. Environmental Health, School of Public Health, Sao Paulo, Sao Paulo, Brazil.*

*2. Epidemiology, School of Public Health, Sao Paulo, Sao Paulo, Brazil.*

*3. Department of Chemistry, Environmental Sciences, Chemical and Pharmaceutical Sciences, Federal University of Sao Paulo, Sao Paulo, Brazil.*

Abstract: Limeira is a Brazilian municipality with 276,000 inhabitants and human development index of 0.775, where is located an important jewelry and fashion jewelry local productive arrangement (LPA). Part of this LPA encompasses precarious and outsourcing informal home practices, which exposes the working families to potentially toxic elements (EPTs: Cd, Cr, Cu, Hg, Ni, Pb, Sn, and Zn). The aim of this study was to compare the prevalence of diseases/health endpoints, which can be related to EPTs exposure, between informal home workers and their relatives, and controls. A cross-sectional study was carried out with exposed group (outsourcing informal home workers and their families, 29 families), and control group (neighbors who did not work with EPTs exposure, 23 families), totaling 254 individuals. A questionnaire on referred diseases, adapted from the household survey of the Brazilian National Cancer Institute, was applied, in order to explore the health perception and referred diseases in this population. For the data analysis, chi-square and Fisher tests were applied ( $p < 0.05$ ). Both exposed and control groups were similar for age, schooling, medication and supplements use, and consumption of alcohol and tobacco ( $p > 0.05$ ). The groups were then categorized according to age (adults and elderly) and women of childbearing age (10 to 49 years). It was observed a higher prevalence of neurological (47.3%), psychiatric (26.4%) and respiratory (34%) diseases in the exposed group, but the statistical differences were not significant. In addition, a statically significant higher prevalence of preterm birth was found for exposed women ( $p = 0.045$ ). The results of this study emphasize the importance of understanding the exposome of the population. Occupational exposure scenarios inside homes should be taken into account to implement public policies to protect the population, especially child-bearing age women. This study was funded by FAPESP (Grant 2016/11087-8) and CAPES.

**P01.3060. A Pilot Project Assessing Exposure of Livestock Workers in the Southwest U.S. to E.Coli O157:H7 and Salmonella**

Rietta Wagoner

*Rietta Wagoner<sup>1</sup>, Daniela Cabrera<sup>2</sup>, Duarte Diaz<sup>2</sup>, Kaitlyn Benally<sup>2</sup>, Gerardo Lopez<sup>2</sup>*

*1. Environmental Health Sciences, College of Public Health , University of Arizona, Tucson, AZ, United States.*

*2. School of Animal and Comparative Biomedical Sciences, University of Arizona, Tucson, AZ, United States.*

Abstract: The livestock industry, like many other agricultural industries in the United States, is dependent on the labor that migrant and seasonal farm workers (MSFW) provide. Infections caused by zoonotic pathogens are commonly underreported or misdiagnosed, and possibly more so in migratory populations that face cultural, structural, legal, financial, and geographic barriers to health services. The objectives of this project were to: Assess feasibility of collecting and analyzing infectious pathogens; inform future risk assessment models; and encourage livestock worker health and safety. Swab samples were collected from the shoulders, knees, and foreheads of employees at two livestock operations at the end of work shift (n=20). The swabs were cultured for E.coli O157:H7 and Salmonella. Molecular Salmonella DNA was extracted and quantified using droplet-digital Polymerase Chain Reaction (ddPCR). Additionally, a questionnaire including demographics, work tasks, and health and safety practices was administered to all participants. E.coli O157:H7 was detected in 13% of cultural environmental samples and Salmonella was detected in 3% of cultural environmental samples. Molecular Salmonella DNA was quantified in 60%, 40% and 15% of samples collected from workers' foreheads, shoulders, and knees, respectively. The majority of participants spoke Spanish and had completed some high school. Finally, all participants reported wearing gloves, an apron, and boots during the workday. The questionnaire provides insight that can be used to create appropriate recommendations for the livestock industry, workers, and workers' families. The positive cultural and molecular samples indicate the need for improved sanitation practices at farms, utilizing the industrial hygiene hierarchy of controls. This pilot project informs future investigations, helps build risk assessment models, improves worker knowledge and health, and fosters preventive practices in the Arizona agricultural industry.

## **P01.3070. Volatile Organic Compound Exposure in Colorado Nail Salons**

Aaron Lamplugh

*Aaron D. Lamplugh<sup>1</sup>, Lupita D. Montoya<sup>2</sup>*

*1. Mechanical Engineering, University of Colorado Boulder, Boulder, CO, United States.*

*2. Civil, Environmental, and Architectural Engineering, University of Colorado Boulder, Boulder, CO, United States.*

Abstract: A pilot study of Volatile Organic Compound (VOC) exposure was conducted in 6 nail salons along Colorado's front range. Measurements included area concentrations of Total VOCs (TVOCs), Formaldehyde (HCHO), Benzene, Toluene, Ethylbenzene, and Xylenes (BTEX), as well as personal exposure sampling of four additional VOCs and worker health surveys. Preliminary data includes average TVOC levels between 3ppm and 22ppm, average HCHO levels between 12ppb and 405ppb, and BTEX concentrations between 23ppb and 300ppb. All participating salons exceeded the NIOSH standard for 8hr time-weighted HCHO concentration on at least one measurement day, and several salons exceeded other HCHO standards including the ACGIH 8hr Threshold Limit Value (TLV). BTEX concentrations observed were similar to those measured in previous occupational exposure studies of gasoline and diesel station attendants and oil refinery workers. Most (65%) survey respondents reported experiencing at least one health symptom as a result of their employment in the nail salon industry, with the most common symptoms including headaches, skin irritation, eye irritation, and nose irritation. Cancer risk estimates for Benzene and Formaldehyde exposure were calculated using cancer slope factors published by the United States Environmental Protection Agency (US EPA) in their Integrated Risk Information System (IRIS). These estimates are based on a 30-year occupational exposure duration, and incorporate average body weights provided by the Center for Disease Control (CDC), as well as inhalation rates provided by US EPA. The elevated lifetime risk for Squamous Cell Carcinoma (SCC) from formaldehyde exposure ranged from approximately 1 in 100,000 ( $1.18 \times 10^{-5}$ ) to over 6 in 10,000 ( $6.5 \times 10^{-4}$ ). The elevated lifetime risk for Leukemia from benzene exposure ranged from  $5.15 \times 10^{-7}$  to  $5.05 \times 10^{-5}$ .

## **P01.3080. Exposure of Nail Salon Workers to Phthalates and Organophosphate Esters**

Jessica Craig

*Jessica Craig<sup>1</sup>, Diana M. Ceballos<sup>2</sup>, Victoria Fruh<sup>1</sup>, Zoe Petropoulos<sup>1</sup>, Joseph G. Allen<sup>2</sup>, Antonia Calafat<sup>3</sup>, Maria Ospina<sup>3</sup>, Xiaoyun Ye<sup>3</sup>, Thomas F. Webster<sup>1</sup>*

*2. Environmental Health, Harvard University T.H. Chan School of Public Health, Cambridge, MA, United States.*

*3. Centers for Disease Control and Prevention, Atlanta, GA, United States.*

Abstract: Nail salons are one of the fastest growing industries in the USA; there is concern about health impacts associated with nail salon exposures in a vulnerable, largely immigrant worker population. Nail technicians are exposed to semi volatile organic compounds including phthalates and organophosphate esters (OPEs). In this pilot study we collected spot urine samples during one work shift from 10 female nail technicians in the Boston (USA) area in 2016-17. We assessed occupational exposures using urinary biomarkers in pre- and post-work shift samples; we compared post-shift concentrations with the general US female population from the National Health and Nutrition Examination Survey (NHANES) 2011-12 for phthalates, 2013-14 for OPEs. We detected 12 phthalate and 4 OPE urinary biomarkers in  $\geq 60\%$  of participants' samples. After creatinine correction, geometric mean (GM) post-shift concentrations were higher than pre-shift for all but one phthalate and one OPE biomarker. Triphenyl phosphate is used as a phthalate replacement in some nail polishes; the GM of its urinary metabolite increased slightly (23%) from pre- to post-shift; post-shift concentrations were slightly higher than NHANES females (17%). The greatest pre- to post-shift change was for mono-2-ethyl-5-carboxypentyl terephthalate (MECPTP), which more than tripled from 11.7 to 36.6  $\mu\text{g/g}$  creatinine. Phthalate biomarkers reported in both studies were lower in our study participants than in NHANES females. NHANES did not report MECPTP, a recent study found increasing trends from 2000-2016 of MECPTP in urine from a convenience sample of US adults. Di-2-ethylhexyl terephthalate (DEHTP), the parent compound of MECPTP, is a plasticizer used as a phthalate substitute in consumer products such as food packaging, toys, and perhaps nail polish. Our results suggest that nail technicians are occupationally exposed to certain phthalates and OPEs, with a urine metabolite of DEHTP showing the largest increase across a work day.

**P01.3090. Occupational Exposure in the Home Environment: An Investigation on Chemical Exposure of Outsourced Informal Working Families Involved in Jewelry and Fashion Jewelry Productive Chain**

Ana Paula Sacone da Silva Ferreira

*Ana Paula Sacone da Silva Ferreira<sup>1</sup>, Elizeu C. Pereira<sup>1</sup>, Fernanda Junqueira Salles<sup>1</sup>, Fabio Ferreira da Silva<sup>2</sup>, Bruno Lemos Batista<sup>2</sup>, Evangelos Handakas<sup>3</sup>, Kelly Polido Kaneshiro Olympio<sup>1</sup>*

Abstract: The city of Limeira presents a relevant productive chain of jewelry and fashion jewelry, including a scenario of outsourcing informal home practices. It is highly complex to understand the potentially toxic elements (PTEs: Ni, Pb, Cd, Sb, Sn, Cu and Zn) exposures of the workers because this productive chain encompasses households. The aim of this study was to investigate the associations between blood PTEs levels (BEL) and informal work in the home environment. In addition, breathing zone air PTEs levels (AL) were measured in welders. This study included 52 families (n= 165), divided into exposed group (n=112) and control group (n= 53). Blood (n=165) of families and breathing zone air samples (n=9) of welders were collected and the PTEs concentrations were determined by inductively coupled plasma mass spectrometry (ICP-MS). Three questionnaires were applied to collect sociodemographic information as well as the details of the workplace conditions and materials used. The overall data were analyzed using principal component analysis (PCA) and analysis of variance (ANOVA). Additionally, a cluster analysis was performed to identify linkage between the data. Finally, multiple logistic regression analysis was carried out in order to gain further insight into a group of observations. We had 9 participants with Cd blood level quantified and the GM was 3.45 µg/L. Cadmium, Ni, and Cu showed AL values up to 10 times higher than occupational guidelines in the air samples analyzed. The results showed a significant difference in the blood Pb levels between exposed and control groups (p<0.05). The PTEs concentrations found in the air raise concern once the families, including children, are in the same exposure scenario. Inadequate work conditions were observed in the houses, revealing the need to implement urgent public actions in order to protect those worker families. This study was funded by FAPESP (Grants: 2016/07457-4;2016/11087-8; 2017/15797-2).

## **P01.3100. Urinary Metabolites of Organophosphate Esters (OPEs) in Electronic Waste Recycling Workers from the Province of Quebec, Canada**

Marc-André Verner

*Inna T. Traore<sup>1</sup>, Sabrina Gravel<sup>3</sup>, Miriam L. Diamond<sup>2</sup>, Liisa Jantunen<sup>5</sup>, Linh V. Nguyen<sup>4</sup>, Congqiao Yang<sup>2</sup>, Sarah Bernstein<sup>2</sup>, Joseph Zayed<sup>1</sup>, France Labrèche<sup>3</sup>, Marc-André Verner<sup>1</sup>*

**Abstract:** Background: Organophosphate esters (OPEs), which are used as flame retardants and plasticizers, have been measured in the air of electronic waste recycling (E-recycling) plants. Numerous studies suggest that exposure to OPEs may result in adverse health effects and constitute a potential health risk for E-recycling workers. However, data on urinary OPE metabolites in occupationally exposed workers is scarce. Objective: To measure urinary OPE metabolites in E-recycling workers and assess their relationship with personal air OPE levels. Methods: Levels of 13 OPE metabolites were measured, at the end of the work shift, in urine samples from 56 workers (four facilities in Quebec, Canada). Air levels of 11 OPEs were measured in 8-hour personal samples with OSHA XAD-2 versatile samplers. The relationship between air OPE levels and urinary metabolite levels was determined using Spearman's rank correlation. Results: Nine of the 13 urinary OPE metabolites were detected in more than 50% of samples. The OPE metabolites with the highest median levels were 1-hydroxy-2-propyl bis (1-chloro-2-propyl) phosphate (OH-BIPCPP) (median: 2.2 ng/mL; maximum: 26), diphenyl phosphate (DPhP) (median: 2.1 ng/mL; maximum: 19), bis(1,3-dichloro-2-propyl) phosphate (BDCIPP) (median: 1.2 ng/mL; maximum: 7.4), and bis(2-chloroethyl) carboxymethyl phosphate (tris(1,3-dichloro-2-propyl) phosphate (BICECMP) (median: 0.5 ng/mL; maximum: 16). Urinary OPE metabolite levels were not significantly correlated with air OPE levels ( $p$  values were above 0.05). Discussion: The median urinary levels of BDCIPP and DPhP were higher than those observed in workers from a Chinese E-recycling site, although the timing of sample collection differed. These findings suggest that workers from E-recycling plants are exposed to OPEs, but that exposure through routes other than inhalation, and possibly non-occupational sources, may be more important contributors to the absorbed dose.

## **P01.3110. Passive Air Sampling for Gaseous Mercury in Workplace Atmospheres and for Personal Inhalation Exposure Monitoring**

Melanie Snow

*Melanie Snow<sup>1</sup>, Ying Duan Lei<sup>1</sup>, Frank Wania<sup>1</sup>*

*1. Department of Chemistry and of Physical and Environmental Sciences, University of Toronto, Scarborough, ON, Canada.*

Abstract: Inhalation exposure to gaseous elemental mercury (GEM) continues to be a concern in a number of workplaces. Examples are facilities handling mercury-containing electronic waste, such as compact fluorescent light bulbs, or so-called "gold-shops" processing the amalgams from artisanal and small-scale gold mining operations. GEM is also often present near historically mercury-contaminated sites or in dental facilities, creating the conditions for low-level, chronic inhalation exposure. Considering that inhaled GEM is readily absorbed and transferred across the blood-brain barrier, there is a need to be able to measure its air concentrations reliably and continuously. We are therefore exploring the feasibility of using a passive air sampler (PAS) recently developed for recording long term average GEM concentrations in the ambient atmosphere in the monitoring of personal GEM inhalation exposure and GEM concentrations in workplace atmospheres. This PAS is small, light, inexpensive, easy-to-operate, and requires no power. By tightly controlling sampling rates through (i) the use of a radial porous diffusive barrier, and (ii) a wind shelter, the sampler achieves high precision and accuracy. Eliminating the PAS's wind shelter allows for its use as a wearable personal sampler, while only slightly increasing sampling rate variability. Average GEM concentrations need to be in excess of  $\sim 20$  ng/m<sup>3</sup> for the PAS to take up sufficient GEM during an 8-hour workday to achieve reliable quantification. For a 40-hour sampling period, corresponding to a traditional workweek, the threshold drops to  $\sim 5$  ng/m<sup>3</sup>. At higher GEM concentrations, (i) even shorter sampling times are achievable, and (ii) a thicker diffusive barrier can be used, which increases precision by better controlling sampling rates. Side-by-side comparisons of the PAS in a number of occupational settings with personal pumped samplers support the validity of using occupational exposure estimates acquired with a PAS.

## **P01.3120. Occupational Safety in Academic Research Laboratories: Identifying Upstream Risk Factors**

Katrina Burns

*Katrina N. Burns<sup>1</sup>, Marie O'Neill<sup>1</sup>, Richard Neitzel<sup>1</sup>, Jon Lillemoen<sup>2</sup>*

*1. Environmental Health Sciences, University of Michigan, Ann Arbor, MI, United States.*

*2. Environment, Health and Safety, University of Michigan, Ann Arbor, MI, United States.*

**Abstract:** **BACKGROUND:** Fatalities and serious injuries in academic research laboratories have resulted in publications of recommendations on reinforcing safety culture, compliance, and safety behaviors in this work environment. However, no systematic review of peer-reviewed literature on academic research laboratories exist. **OBJECTIVES:** This review assesses literature on U.S. university research laboratories from 2008 through 2017, tort case decisions, and incident investigation results by comparing to the current recommendations for improving safety culture in academic research laboratories from the National Research Council (NRC), American Chemical Society (ACS), and Association of Public Land Grant Universities (APLU). **METHODS:** Search terms derived from three publications were entered in PubMed, ProQuest, and Web of Science databases. A scoping review was used to map the studies related to this topic. Google Scholar was used to find tort cases. Incident investigation results were found through published news articles or on the Occupational Safety and Health Association (OSHA) website. **RESULTS:** 223 peer review articles were found; 5 articles on specifically referencing academic research laboratories, including seminal articles; 104 articles were focused on interventions in various work environments, including healthcare; 114 were nonintervention studies; 12 examples of tort cases involving academic research laboratories were also found. **DISCUSSION:** The literature on occupational safety in academic research laboratories is relatively sparse, not surprising given evidence that adverse safety incidents and near misses are under-reported in these settings, and incentives to improve safety culture and establish safety management systems are lacking. However, literature representing other work environments identified additional upstream factors useful for a framework on promoting safety culture in the academic research laboratory workforce.

**P01.3130. Associations between Psychosocial Working Environments and Nurses' Eating Behaviors in Taiwan: A Pilot Study**

Ting-Ti Lin

*Ting-Ti Lin<sup>1</sup>, Judith Shu-Chu Shiao<sup>2</sup>, Yi-Ting Lin<sup>2</sup>, Yi-Chuan Chen<sup>2</sup>, Yue Leon Guo<sup>3</sup>*

*1. College of Nursing, University of Illinois at Chicago, Chicago, IL, United States.*

*2. School of Nursing, National Taiwan University, Taipei, Taiwan.*

*3. National Institute of Environmental Health Sciences, National Health Research Institutes, Zhunan, Taiwan.*

**Abstract:** Background: Previous studies revealed that psychosocial working environments (e.g., occupational stress, and shift work) might contribute to workers' unhealthy eating behaviors. However, the effects among hospital nurses working a shift work pattern remain inconclusive. Objective: To examine the associations between nurses' psychosocial working environments and their eating behaviors. Method: Using a cross-sectional study design, a mailed structured self-administered questionnaire was administered to collect RNs' exposures to psychosocial working environments (i.e., perceived occupational stress, nurse-patient ratio, and weekly working hours) and their eating behaviors during a typical shift (i.e., customized handmade drinks, sweetened beverages, and sweetened food). Multivariable logistic regressions were employed to analyze associations between RNs' psychosocial working environments and eating behaviors. Results: A total of 509 questionnaires were eligible for the final analysis. The prevalence rates of RNs' customized handmade drinks, sweetened beverages, and sweetened foods intake during their typical shifts were 77.2%, 55.8%, and 50.7%, respectively. Unexpected work-related events during shifts were significantly associated with RNs' consumptions of customized handmade drinks (AOR: 1.7, 95% CI: 1.1, 2.6) and sweetened beverages (AOR: 1.7, 95% CI: 1.1, 2.4). RNs working more than 48 hours weekly were at a higher likelihood of sweetened beverage consumptions (AOR: 1.8, 95% CI: 1.1, 2.9). Unreasonable nurse-patient ratio (AOR: 1.4, 95% CI: 1.0, 2.5) and perceived occupational stress (AOR: 2.0, 95% CI: 1.2, 3.7) were associated with RNs' sweetened food intakes. Conclusion: This study revealed that psychosocial working environments were related to hospital RNs' certain types of food intakes during their typical shifts. Strategies to reduce hospital RNs' care burden and demands may be beneficial in improving hospital RNs' food choices.

**P01.3140. Urinary MDA and 8-OHdG Concentrations among Agricultural Workers in South Korea and Influence of Protective Measures**

*3. Department of Occupational and Environmental Health, Yongin University, Yongin-si, Gyeonggi-do, Korea (the Republic of).*

Abstract: Pesticides increase the quality of agricultural products, however routine exposure to these chemicals can result in adverse chronic health effects. Oxidative stress biomarkers such as malondialdehyde (MDA) and 8-hydroxy-2'-deoxyguanosine (8-OHdG) have been used to link pesticide exposure with the risk of chronic diseases such as cancer and neurological diseases. In the present study, the levels of MDA and 8-OHdG were analysed in urine samples collected from agricultural workers in South Korea. The influence of wearing personal protective equipment and performing protective behaviors on the levels of these two biomarkers was also evaluated. The median levels of MDA and 8-OHdG in urine samples were 9.37 nmol/mg creatinine and 19.06 ng/mg creatinine, respectively. In general, the levels of MDA and 8-OHdG were higher in male farmers. Wearing greater numbers of personal protective equipment and performing more protective behaviors was significantly associated with lower levels of MDA and 8-OHdG. The results indicate that pesticide exposure could cause oxidative stress and DNA damage in agricultural workers, and protective measures are important for reducing the levels of MDA and 8-OHdG.

## **P01.3160. Artisanal Tanning Industry and Health in Bogota, 2017**

Danyver Carreazo Vasquez

**Abstract: SUMMARY** The process of tanning, which transforms animal skin into leather through the application of chemical products, can have deleterious effects on human health. Half of tannery factories in Bogotá are not legally registered so there is a lack of control on the use of harmful substances in the process as chromium or phthalates. This study was conducted to identify health effects associated with environmental exposure to substances produced by the tanning industry in San Benito, which is a community with high concentration of tannery factories in Bogota. Cross-sectional study, sample of 265 people from San Benito neighborhood (exposed) and another not exposed neighborhood. Exposure criteria was defined as proximity to the tanning industry in a radius of 300 meters. Outcome measures were dermatological, respiratory and neurological sentinel symptoms and diseases related to the exposure. Data was collected via survey through an instrument validated both by experts and statistically. Statistical analysis included the calculation of prevalence ratio and confidence intervals. Statistically significant associations were observed for chronic bronchitis (PR: 1.39 IC95%: 1.05-1.84), contact dermatitis (PR: 1.19, 95% CI: 0, 75-1.90) migraine (PR: 1.30 IC95%: 1.30-1.65), nasal congestion (RP: 1.71, 95% CI: 1.19-2.47), cough with phlegm (RP: 2.04 IC95%: 1.19-3.50) and headache (RP: 1.30 IC95%: 1.03-1.65). An excess morbidity was observed in highly exposed population. Further studies should examine the causal effect of specific toxic substances on population health.

## **P01.3170. Acute Pulmonary Responses among Wildland Firefighters following Exposure to Wildland Fire Smoke**

Chieh-Ming Wu

*Chieh-Ming Wu<sup>1</sup>, Anna Adetona<sup>2</sup>, Luke Naeher<sup>3</sup>, Olorunfemi Adetona<sup>1</sup>*

*2. Battelle Memorial Institute, Columbus, OH, United States.*

*3. Department of Environmental Health Science, College of Public Health, University of Georgia, Athens, GA, United States.*

**Abstract:** Background: Wildland firefighters are repeatedly exposed to elevated levels of wildland fire smoke (WF smoke) while protecting lives and properties from wildland fires. Although association between WF smoke exposure and spirometric changes has been reported in a few epidemiological studies, knowledge of pulmonary biochemical changes underlying such physiological response is still limited. Studies using nasal or sputum lavage for investigating pulmonary effects indicate WF smoke exposure can induce oxidative stress and inflammation among the firefighters. However, these collection methods are either non-representative or invasive. Methods: In the present study, exhaled breath condensate (EBC), a non-invasive collection method, was used to determine pulmonary responses among wildland firefighters working at prescribed burns. Twelve firefighters were recruited from US Forest Service-Savannah River Site. EBC was collected before (pre-shift), immediately after (post-shift), and morning after work shifts for measuring oxidative stress (8-isoprostane) and pro-inflammatory responses (Interleukin-8 [IL-8]; C-reactive Protein [CRP]; and Intercellular Adhesion Molecule 1 [ICAM-1]). Linear Mixed Effect Model was used to determine ratio of post to pre-shift and ratio of morning after to pre-shift of the biomarkers. Results and conclusions: Marginally significant increases were observed from pre- to post-shift for sICAM-1 (4%; p-value = 0.08) and 8-isoprostane (9%; p-value = 0.09). No other significant changes of the biomarkers were observed. Results suggest that WF smoke exposure causes mild pulmonary responses among wildland firefighters as indicated by small increases in the levels of sICAM-1 and 8-isoprostane following exposure. Results from this study might indicate the mechanism underlying lung function decline or systemic responses reported by epidemiological studies investigating association between WF smoke exposure and acute health effects among the firefighters.

**P01.3171. Influence of Genetic Variance on Occupational Exposure to 1,6-Hexamethylene Diisocyanate (HDI) and Its Trimer HDI Isocyanurate**

Laura Taylor

*Laura W. Taylor<sup>1</sup>, John E. French<sup>2</sup>, Jayne C. Boyer<sup>1</sup>, Leena A. Nylander-French<sup>1</sup>*

*2. Nutrition Research Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States.*

Abstract: Polyurethane spray-painting can result in significant occupational exposure to 1,6-hexamethylene diisocyanate (HDI) monomer and its trimer, HDI isocyanurate. Inter-individual genetic differences have been linked with adverse health effects and asthma risk in isocyanate-exposed workers. However, little is known about inter-individual differences in response to HDI isocyanurate exposure compared to the HDI monomer. We are investigating the similarities and differences in exposure-dose responses and the genetic variants that modify or predict relationships between toxicokinetics and biomarker levels in exposed workers. Inhalation and skin exposure to HDI monomer and HDI isocyanurate were measured in 33 spray-painters along with the respective urine and blood biomarkers of 1,6-hexamethylene diamine (HDA) and trisaminohexyl isocyanurate (TAHI). Genome-wide microarrays (Affymetrix 6.0) were used to genotype the workers' single nucleotide polymorphisms (SNPs) and to conduct a genome-wide association study (GWAS). Using exposure values as covariates and a false discovery rate <0.20 for significance, GWAS showed that one SNP was associated with TAHI levels in urine, six SNPs were associated with HDA in plasma, and twelve SNPs were associated with HDA levels in urine. No SNP associations reached significance for TAHI levels in plasma. The SNPs were tested in linear mixed models (LMM) and bioinformatics data of the genes proximal to the top ten most significant SNPs for each compound were assessed for biological plausibility. Bioinformatics for HDI monomer associated SNPs included predicted interactions involving signal transduction and the immune function. Bioinformatics for HDI isocyanurate predicted interactions for cell signaling, structure, and adhesion. We demonstrate that genetic variance impacts the biomarker levels in workers exposed to HDI monomer and HDI isocyanurate, and that HDA and TAHI levels can be used to refine exposure prediction models for both compounds.

**P01.3172. Personal and Area Exposure Assessment at a Stainless Steel Fabrication Facility: Evaluation of Inhalable, Thoracic, Time-Resolved PM<sub>10</sub>, and Lung-Deposited Airborne Metals**

Ashley Newton

*3. Environmental Health Associates, Denver, CO, United States.*

Abstract: Occupational exposure to multivalent transition metals in welding fume is associated with a variety of adverse health outcomes, including respiratory and cardiovascular impairment, lung cancer, and metal fume fever. Welding fume was designated a Group 1 carcinogen by an International Agency for Research on Cancer (IARC) working group in 2017 and a lack of data on deposition and clearance of welding fume was identified as a gap in the scientific literature. We conducted a detailed exposure assessment of 18 welders (monitoring two work shifts per person) in a stainless steel fabrication facility, evaluating personal exposure to inhalable and lung-deposited PM and airborne metals as well as area thoracic PM and time-resolved PM<sub>10</sub> airborne metals. Urinary metals biomarkers were also measured pre and post shift. Mean area thoracic PM exposure in each of the three shops was 30.1, 214, and 164  $\mu\text{g}/\text{m}^3$ , respectively on the first day of sampling. During all sampled shifts, 14 area PM<sub>10</sub> airborne metals were measured with 15 minute time resolution and concentration time-series were produced for each day. In the largest shop, mean area chromium exposure was 19.5  $\mu\text{g}/\text{m}^3$ , mean area manganese exposure was 32.3  $\mu\text{g}/\text{m}^3$ , and mean nickel exposure was 5.8  $\mu\text{g}/\text{m}^3$  over the measured shift. Lead, tungsten, copper, molybdenum, and vanadium exposure were all highly variable, exhibiting short-duration peaks of varying intensities. Although there is currently no quantitative occupational exposure limit for welding fume, the workers at this facility were exposed to high levels of inhalable PM and metal-specific welding fume components within biologically relevant size fractions.

**P01.3173. Assessing Diesel Particulate Matter Exposure by a Multi-Metric Approach in Three Different Workplaces in Québec, Canada**

Alan da Silveira Fleck

*Alan da Silveira Fleck<sup>1</sup>, Cyril Catto<sup>1</sup>, Caroline Couture<sup>1</sup>, Maximilien Debia<sup>1</sup>*

*1. Department of Environmental and Occupational Health, Université de Montreal Public Health Research Institute, School of Public Health, Université de Montreal, Montreal, QC, Canada.*

Abstract: Elemental carbon and total carbon are the surrogates usually used to assess diesel particulate matter (DPM) exposure, but the measurement of different indicators by direct-reading instruments (DRI) is also described and includes advantages and limitations. The aim of this study was to assess and compare several indicators of DPM exposure in three workplaces by using a multi-metric approach. Three workplaces in Quebec (Canada) were evaluated: An underground mine (W1; n=12), a subway tunnel (W2; n=12) and a truck repair workshop (W3; n=12). Ambient particle number concentration (PNC), submicron particulate matter (PM1), and submicron elemental carbon (EC1-DRI) were measured by DRI. Filter-based samples (FBS) were also collected to estimate the respirable and submicron fractions of elemental carbon (ECR and EC1-FBS), as well as the respirable and submicron fractions of total carbon (TCR and TC1). The geometric means of the DRI were: 128,000; 32,800 and 22,700 particles/cm<sup>3</sup> for PNC in W1, W2 and W3, respectively; 165, 20.4 and 6.9 µg/m<sup>3</sup> for PM1; and 148, 25 and 4.1 µg/m<sup>3</sup> for EC1-DRI. W1 also had the highest concentrations of ECR, EC1-FBS, TCR and TC1. EC1-DRI showed the strongest association with EC1-FBS when considering all workplaces ( $\rho = 0.966$ ;  $p < 0.001$ ), but this association decreased at lower concentrations of DPM. PM1 ( $\rho = 0.936$ ;  $p < 0.001$ ) and PNC ( $\rho = 0.871$ ;  $p < 0.001$ ) also showed a strong positive correlation with EC1-FBS. Ratios of 1.05, 1.76 and 1.30 were calculated between TC1/PM1 for W1, W2 and W3, respectively. This study provided solid information about the concentrations, as well as their associations, of several indicators of DPM exposure in three different exposure contexts.

**P01.3174. Use of Geocoding to Understand Variation in Neighborhood Socioeconomic Status in a Nationwide Occupational Cohort across Time, Space and Demographic Characteristics**

Gabriela Bustamante Callejas

*Gabriela Bustamante Callejas<sup>1</sup>, Theresa Osypuk<sup>2</sup>, Cari Kitahara<sup>3</sup>, Richard Maclehose<sup>2</sup>, Marizen Ramirez<sup>1</sup>, Martha Linet<sup>3</sup>, Bruce Alexander<sup>1</sup>*

*1. Environmental Health Sciences, University of Minnesota, Falcon Heights, MN, United States.*

*2. Epidemiology, University of Minnesota, Minneapolis, MN, United States.*

*3. NIH/NCI, Rockville, MD, United States.*

Abstract: Geocoding has been used in environmental epidemiology to understand geographically patterned exposures but has not been widely applied in occupational studies. We present the feasibility of geocoding a nationwide occupational cohort, the US Radiologic Technologists Study (USRT, N=146,021) to: (1) evaluate geocoding across time, (2) test precision of geocoding by rural (vs. urban) status and by neighborhood socioeconomic status (nSES), and (3) explore nSES distribution by some cohort demographic factors. We created a standardized nSES index, based on validated methods, for each census block-group in the US, at 3 time points, using 6 items from the U.S. Census (1990, 2000) and American Community Survey (2010): regionally-adjusted median household income and median housing value, % households with interest/income, % adults who completed high school, % adults who completed college, and % employed persons in managerial occupations. To link nSES to the cohort, we geocoded respondent addresses in 1992, 2003, 2010, to block-group of residence. Over 99% of addresses were geocoded; 76 to 86% were mapped to an address-specific block-group, while the rest were geocoded to a block-group of the zipcode centroid. Urban (vs. rural) addresses and those in the highest (vs. lowest) nSES quintile were more likely to be geocoded to an address-specific block-group (OR=4.6; 95%CI=4.5-4.7 and OR=6.4; 95%CI=6.1-6.7, respectively for 1992 addresses). Results of linear regression show higher nSES in 1990 was associated with USRT participants of female gender ( $\beta=0.22$ ; 95%CI=0.20, 0.23), older age ( $\beta=0.003$ ; 95%CI=0.002, 0.003), white race ( $\beta=0.37$ ; 95%CI=0.35, 0.38) and more recent age-adjusted certification year ( $\beta= -0.018$ ; 95%CI= -0.016, -0.019). Similar results were obtained for other years. This analysis indicates geocoding can describe neighborhood characteristics within the USRT which may be related to diseases linked to occupational exposures like cancer and cardiovascular disease.

**P02.0010. The 2008 Recession, Human Mortality and Its Changing Relationship with Daily Temperatures in Europe**

Joan Ballester

*Joan Ballester<sup>1</sup>, Jean-Marie Robine<sup>2</sup>, François Richard Herrmann<sup>3</sup>, Xavier Rodó<sup>1</sup>*

- 1. Barcelona Institute for Global Health (ISGlobal), Barcelona, Catalonia, Spain.*
- 2. Institut National de la Santé et de la Recherche Médicale (INSERM), Montpellier, France.*
- 3. University Hospitals and University of Geneva, Geneva, Switzerland.*

**Abstract:** Background. Previous studies have consistently shown the recurrent relationship between macroeconomic cycles and changes in mortality trends during the twentieth century, so that recessions are generally associated with periods of faster life expectancy rise, and periods of economic growth with slower reductions or even increases in mortality trends. These changes have been traditionally associated with a reduction in bad habits, environmental pollution and driving and occupational accidents due to decreased economic activity and employment. Methods and Findings. Here we analyze the link between annual gross domestic product estimations and daily atmospheric temperatures and counts of death for a large ensemble of European regions to describe the effect of the 2008 recession on all-cause human mortality trends. Results show that the regions and countries with the largest (smallest) economic slowdown correspond to those with the largest (smallest) acceleration of the decreasing mortality trend. Our analysis with daily temperature and mortality counts shows that the largest relationship between macroeconomic cycles and mortality trends is observed for the cold half of the year and, to a lower extent, in July and August, while it is smallest for temperatures around the point of minimum mortality. Conclusions. Our study shows the strong interregional association between macroeconomic fluctuations and mortality trends through a continental comparison for the 2008 recession in Europe. Daily climate and mortality data revealed for the first time that this association also depends on the annual cycle of temperatures, and therefore, on the seasonal timing of the underlying causes of death. Results suggest that the relationship between macroeconomic cycles and mortality trends might change as a result of the current context of rising temperatures and an eventual adaptive response of societies.

## **P02.0020. Does Climate Matter? How Temperature and Precipitation Affect the Relationship between Neighbourhood Walkability and Walking for Transportation**

Justin Thielman

*Justin Thielman<sup>1</sup>, Maria Chiu<sup>2</sup>, Laura Rosella<sup>3</sup>, Ray Copes<sup>4</sup>, Heather Manson<sup>1</sup>*

*3. Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada.*

*4. Environmental and Occupational Health, Public Health Ontario, Toronto, ON, Canada.*

Abstract: Previous research has found associations between neighbourhood walkability and transport walking, which has health benefits. However, the influence of climate on these associations is poorly understood. Our objective is to examine how climate modifies the association between walkability and walking to work or school across Canada. We hypothesize that this association is weaker in areas with more extreme climates. The study population is from the 2007-2014 Canadian Community Health Surveys, ongoing cross-sectional surveys of Canadians aged 12 and up. We excluded people who lived in rural areas or did not work or attend school. These surveys collect self-reported data on socio-demographics and transport walking. Climate data are 1981-2010 climate normals from weather stations across Canada and walkability data are Walk Score® values of respondents' residential locations. We estimated associations between walkability (split into quintiles) and energy expenditure on walking to work/school, adjusting for socio-demographics. To examine how climate modifies this association, we will incorporate the following variables into these models: mean temperature in hottest and coldest months, mean precipitation in wettest and driest months, days per year and degree days over and under specific temperatures. The mean energy expenditure on walking to work/school was 0.26 kcal/kg/day among people in the highest walkability quintile, compared to 0.08 kcal/kg/day in the lowest quintile. After adjusting for socio-demographics, the difference in energy expenditure was 0.17 kcal/kg/day (95% confidence interval [0.15-0.18]). Climate variables will be incorporated into these models, with results forthcoming. On average, people living in more walkable neighbourhoods walk to work or school more than people in less walkable neighbourhoods. Incorporation of climate variables into this analysis will inform whether climate should be considered when evaluating walkability and physical activity.

## **P02.0030. Impacts of High Temperature on Adverse Birth Outcomes in Seoul, Korea: Disparities by Individual- and Community-Level Characteristics**

Jiyoung Son

*Jiyoung Son<sup>1</sup>, Jong-Tae Lee<sup>2</sup>, Kevin Lane<sup>3</sup>, Michelle Bell<sup>1</sup>*

- 2. Korea University, Seoul, Korea (the Republic of).*
- 3. Boston University, Boston, MA, United States.*

**Abstract:** Introduction: Relatively few studies examined the effect of temperature on adverse birth outcomes and effect modifiers of these associations. We investigated associations between heat exposure and adverse birth outcomes and evaluated how individual and community characteristics affect these associations using birth data in Seoul, Korea, 2004-2012. Methods: Logistic regression was applied to estimate the association between heat index during pregnancy, 4 weeks before delivery, and 1 week before delivery and adverse birth outcomes (preterm birth and term low birth weight). Models were adjusted for infant's sex, mother's age, mother's educational level, birth year, birth month, and air pollution level. We investigated effect modification by individual (infant's sex, mother's age and educational level) and community characteristics (gu-level SES and percentage of green areas of residential address). We also evaluated associations by combinations of individual- and community-level SES. Results: An interquartile range increase (5.5°C) in heat index during pregnancy, 4 weeks before delivery, and 1 week before delivery was associated with an odds ratio of 1.033 (95% CI 1.005, 1.061), 1.019 (95% CI 1.010, 1.029), and 1.018 (95% CI 1.009, 1.027) for preterm birth, respectively. We did not find significant associations with term low birth weight. Higher risk of heat on preterm birth was associated with some individual characteristics such as infants with younger or older mother and lower community-level SES. For combinations of individual- and community-level SES, the highest and most significant estimated effect was for infants with low educated mothers living in lower community-level SES. Conclusions: Our findings have implications for the protection of infants from high heat and for future studies evaluating impacts of high temperatures on adverse birth outcomes. Our results help identify which subpopulations and factors are most relevant for disparities in this association.

## **P02.0040. A Systematic Review and Meta-Analysis of the Association between Daily Mean Temperature and Mortality in China**

Qianlai Luo

*Qianlai Luo<sup>1</sup>, Shanshan Li<sup>2</sup>, Yuming Guo<sup>2</sup>, Jouni Jaakkola<sup>1</sup>*

*1. Center for Environmental and Respiratory Health Research (CERH), University of Oulu, Oulu, Finland.*

*2. School of Public Health and Preventive Medicine, , Monash University, Melbourne, VIC, Australia.*

**Abstract:** Introduction: We summarized the evidence of the effects of exposure to hot and cold temperatures on mortality in China. We included studies published in Chinese and English. Materials and methods: We conducted a systematic search of peer-reviewed studies published up to the end of 2016 on daily mean temperature and mortality. Studies were drawn from four English databases- PubMed, MEDLINE, SciVerse Scopus, and Web of Science- as well as one Chinese database, China Knowledge Resource Integrated Database (www.cnki.net). The effect estimates of heat/cold were converted to relative risks (RR) associated with 1 degree increase/decrease beyond the heat/cold reference temperatures. For studies that provided lag-specific estimates, we used both the maximum and minimum of RR estimates. Summary effect estimates for all-cause and cause-specific mortalities, as well as RRs stratified by sex, age, and socio-economic status were calculated. We also investigated patterns of adaptation to hot and cold temperatures at different latitudes and at different reference temperatures. Results: We included a total of 34 articles in this systematic review and meta-analysis. For 1 degree temperature decrease/increase beyond reference points, the risk of non-accidental mortality increased by 3% (RR, 1.03; 95% CI [1.03-1.04]) for cold and 2% (RR, 1.02; 95% CI [1.02-1.03]) for heat, respectively. The risk of cause-specific (cardiovascular, respiratory, cerebrovascular) mortalities increased between 3% and 4% for cold and between 3% and 4% for heat. We identified variation in optimal temperature range related to latitude of the residential area, and differences in people's ability to adapt to heat versus cold. Conclusion: We found consistent evidence of the association between temperature and mortality, as well as evidence of patterns in human adaptation. We discussed implications of these findings for China and for future research activities.

## **P02.0050. Patterns of Environmental Displacement in Indonesia**

Michelle Bell

*Kate Burrows<sup>1</sup>, Jiyoung Son<sup>1</sup>, Michelle Bell<sup>1</sup>*

*1. Forestry and Environmental Studies, Yale University, New Haven, CT, United States.*

**Abstract:** Climate change has the potential to impact global migration patterns which can in turn impact public health. Recent research has been conducted linking large-scale population movement to changes in temperature and precipitation. However, few studies have looked at individual-level differences between those who move for environmental reasons, for non-environmental reasons, and those who do not move at all. It is critical that we understand individual and household-level heterogeneity across migrants and non-migrants in order to more fully understand migratory responses to environmental drivers. This project uses Indonesian household survey data from movers and non-movers for environmental and other causes to address two primary objectives: first, to explore differences in demographics and socioeconomic status, and second, to understand characteristics of the moves themselves. We found that environmental migrants tended to be significantly older, less educated, more likely to be married, and more likely to be female than their non-environmental counterparts. This suggests that migration for environmental purposes is generally undertaken as a family, which contrasts with findings from other regions that show increased rates of young, male household members migrating as a means to diversify income after droughts and other environmental stressors. We also found that environmental moves were generally made over shorter distances and were less likely to cross provincial borders than non-environmental moves, supporting previous research that environmental migration tends to be localized. To mitigate the negative effects of climate change, we must better understand how environmental factors are already influencing migratory patterns. This research provides some insight into this issue in Indonesia. Further work is needed to better explore how environmental stressors affect the migration decision making process and to understand how this displacement affects public health.

**P02.0060. Vulnerability to the Cardiovascular Effects of Ambient Heat in Six U.S. Cities: Results from the Multi-Ethnic Study of Atherosclerosis (MESA)**

Carina Gronlund

*Carina Gronlund<sup>1</sup>, Lianne Sheppard<sup>2</sup>, Sara Adar<sup>1</sup>, Marie O'neill<sup>1</sup>, Amy Auchincloss<sup>3</sup>, Jaime Madrigano<sup>4</sup>, Joel D. Kaufman<sup>2</sup>, Ana Diez Roux<sup>3</sup>*

- 4. RAND Corporation, Arlington, VA, United States.*

**Abstract:** Background: With climate change, temperatures are increasing. Heat-associated health events disproportionately affect certain subpopulations. However, prior research has often lacked information on individual-level health and air conditioning (AC) and neighborhood stressors/protections. Objectives: To assess whether 1) heat (two-day mean temperature above the local 75th percentile), is associated with increased heart rate and decreased blood pressure, controlling for age, time, season, daily ozone and daily particulate matter (PM<sub>2.5</sub>), and 2) associations differ by anti-hypertensive-medication use, renal function, fasting glucose, emotional support, AC ownership and use, normalized difference vegetation index, neighborhood safety and residence-specific oxides-of-nitrogen and PM<sub>2.5</sub> exposure. Methods: Health and behavioral characteristics were obtained repeatedly on participants of the Multi-Ethnic Study of Atherosclerosis in six U.S. sites (2000-2010). These were linked with airport temperature, air quality, and satellite- and survey-derived neighborhood characteristics. We used a fixed-effects design, regressing health outcomes on linear temperature splines with knots at the city-specific 75th percentiles, interaction terms for each characteristic, and adjustment for month-of-year, age, PM<sub>2.5</sub> and ozone. Results: For a 2-degree-Celsius increase in heat, systolic blood pressure (SBP) decreased by 1.1 mmHg (95% CI: -1.6, -0.6) and diastolic blood pressure by 0.3 mmHg (95% CI: -0.6, -0.1). Among individuals not using anti-hypertensive medications, heat-associated decreases in SBP were 2.1 mmHg greater among individuals with central AC vs. without. The remaining modifiers were not significant after multiple-comparisons corrections or in sensitivity analyses. Conclusions: Outdoor heat is associated with decreasing blood pressure, and cardiovascular vulnerability may vary primarily by central AC ownership.

Abstract: Climate-change (C-C) health effects are among the most challenging concerns in our future. The health impacts are currently not well assessed through current statistics. In particular, activities by clinicians in relation to environment and health are still rather underdeveloped. We carried out a systematic bibliographic review on Sentinel Physician Networks. These were considered in numerous articles (6691 from 1984 to 2017), but very few dealt with environmental-health (EH) issues (just 14 in the same period). Thus we propose the development of a structured system, aimed at monitoring the effects of environmental issues critical for population health, both by raising awareness and by reporting any situation raising concerns. In fact we believe that Family Doctors (FDs) and Pediatricians (PEDs) could play a crucial role in putting global concerns in connection with local actions. As such three two-day courses were staged in Italy to train 61 FDs/PEDs, and covering the following issues: i) C-C health effects, ii) Statistics and environmental epidemiology, iii) EH bibliographic data-bases, iv) Communication and advocacy, v) Educational methods. A quantitative evaluation was carried out and 100% of trainees agreed to join a systematic training platform to further develop their skills in EH issues. A Sentinel Physicians for the Environment (SPE) Manual is underway. Due to scarcity of experiences across the world, an agreement with the World Health Organization (WHO) Public Health and Environment Dpt. was reached to develop fact sheets to share and disseminate awareness and skills in this field. An international panel of expert has been established. The main aim of this collaboration is the definition of a list of criteria to guarantee sound science, authoritativeness and collaboration at all institutional levels. This proposal in collaboration with WHO could contribute to improving environment and health especially in deprived areas.

## **P02.0080. What can STP Geographies Tell us About the Impact of the Cold Weather Plan for England?**

Peninah Murage

*Peninah Murage<sup>1</sup>, Shakoor Hajat<sup>1</sup>*

*1. Public Health Environment and Society, London School of Hygiene and Tropical Medicine, London, United Kingdom.*

**Abstract:** Background The Cold Weather Plan (CWP) for England was introduced in 2011 to prevent the adverse health effects of cold weather, however, its impact is currently unknown. This study compares cold risk before and after the CWP implementation, and the distribution in risk at the level of the newly formed STP (Sustainability Transformation Partnerships); this is in recognition of STPs' central role in delivering the NHS transformation agenda. Methods We used daily mean temperatures and mortality count from four years preceding and following CWP implementation (2007-2010 and 2012-2015). Time series regression was used to model cold effect for up to 28 days, and relative risk was estimated for all-cause, disease and age-group specific mortality. Fuel poverty statistics were used to indicate mitigation against cold exposure. Area distribution in risk and fuel poverty were mapped, and STPs with lower than median decline in risk, and higher than average fuel poverty were highlighted. Results Comparing relative risk before and after implementation revealed a significant decline in risk for those aged 0-64 years (RR 1.34, 1.23-1.45, to, 1.09, 1.00-1.19). STP variation in risk was higher in the period following implementation ( $I^2$ , 72.1% vs. 56.2%), additionally, risk increased in a third of STPs; Cornwall and the Isles of Scilly (RR 2.35, 1.72-3.21) and South West London (RR 1.19, 0.97-1.47) had the highest and lowest risk in the more recent period. By combining risk and fuel poverty information, we identified 14 STPs where the need to address cold risk on health remains. Conclusions The national decline in risk in the youngest age group is welcomed and maybe linked to the application of CWP. However, area variations in risk, which increased after 2011, may be attributed to local differences in fuel poverty, and to the implementation of the level 1 (year-round planning) of the CWP.

## **P02.0090. Temperature-Related Mortality in Latin America: A Multi-City Multi-Country Study**

**Abstract:** Background Attributable mortality risk for heat and cold has been investigated in Europe and North America. However, none so far has provided estimates for Latin American, with a whole temperature range in different climates. We aimed to estimate the mortality attributable to heat and cold in the Latin American countries participating in the Multi-City Multi-Country Collaborative Research Network, and study their heterogeneity of effects by climatic zones. Methods We collected data for 40 cities in Argentina, Brazil, Chile, Colombia and Mexico, between 1997-2015, totalling over 9 million deaths. We conducted a two-stage approach. Firstly, we estimated city-specific temperature-mortality associations using quasi-Poisson regression with distributed lag non-linear models with 21 days of lag. We calculated attributable deaths for heat and cold above and below the city-specific minimum mortality temperature using cutoffs at the 2.5th and 97.5th temperature percentiles. Next, we combined city-specific estimates using meta-regression including indicator variables for the country and climatic zone. Results More temperature-attributable deaths were caused by cold (4.1%, 95%CI=[3.2 to 5.0%]) than by heat (0.7%, 95%CI=[0.4 to 0.9%]). This was observed consistently in all countries. Larger mortality was attributable to cold in dry and temperate than in tropical climates. While for heat, attributable mortality was larger in dry than in tropical and temperate climates. Discussion Most of the temperature-related mortality burden in Latin American is attributable to the contribution of cold and mainly observed in dry climates. This could be of relevance to developing public-health interventions in the region to minimize the adverse health effects of temperatures. On behalf of the MCC Collaborative Research Network.

## **P02.0100. Temperature and Term Low Birth Weight in California**

*1. Air and Climate Epidemiology Section, Cal EPA/OEHHA, Oakland, CA, United States.*

*2. Environmental Health Sciences, UC Berkeley, Berkeley, CA, United States.*

Abstract: Few investigations have explored adverse birth outcomes from temperature exposure. In a retrospective cohort study conducted in California from 1999 to 2013, we examined apparent temperature, a combination of temperature and relative humidity, and term low birth weight (LBW) among 43,629 full-term LBW infants and 2,032,601 normal weight infants. Birth certificate data were provided by the California Office of Vital Statistics and meteorologic data came from the California Irrigation Management Information System, US EPA, and National Climatic Data Center. After considering several apparent temperature metrics, we observed the greatest associations between term LBW and exposures over the full gestation (13.0%; 95% confidence interval: 4.1, 22.7% per 10 degrees Fahrenheit (°F) increase in apparent temperature) above 55°F and third trimester exposure above 60°F (15.8%; 5.0, 27.6%). Greater apparent temperature exposure during the first month of pregnancy exhibited no significant risk, while the first trimester had a significantly negative association, and second trimester, last month and last two weeks had slightly increased risks. Mothers who were Black, older, delivered male infants, or gave birth during the warm season conferred highest risks. This study provides further evidence for risks of adverse birth outcomes from high temperatures for pregnant women, particularly for vulnerable subgroups.

## **P02.0110. Associations between Ambient Air Temperature, Low Birth Weight and Small for Gestational Age in Term Newborns in Southern Israel**

Raanan Raz

*Itai Kloog<sup>2</sup>, Lena Novack<sup>4</sup>, Allan Just<sup>3</sup>, Raanan Raz<sup>1</sup>*

- 4. Department of Public Health, Ben-Gurion University of the Negev, Beer Sheva, Israel.*

**Abstract:** Background: Relatively few studies have examined the association between extreme ambient air temperatures (Ta) and pregnancy outcomes. We investigated the association between Ta, term low birth weight (tLBW) and small for gestational age (SGA) in singleton term infants, using a decade (2004-2013) of regional hospital data in southern Israel. Methods: We linked all births in Soroka University Medical Center in the southern district of Israel and insured by Clalit Health Services with pregnancy Ta, estimated by a hybrid satellite-based spatio-temporally model. Analyses were adjusted for calendar month, year, maternal age, gravidity, parity, ethnicity, sex, poverty index and population density. Results: The study population included 56,141 newborns, with 1,716 (3.1%) cases of tLBW and 8,634 (15.4%) cases of SGA. The average and the median daily Ta across the entire pregnancy were 19.9 (range: 14.6-24.9) degrees centigrade. The lowest Ta quartile was associated with higher risk of tLBW (OR = 1.38, 95%CI 1.16-1.64) while the highest Ta quartile was not significantly associated with tLBW (OR = 1.12, 95%CI 0.96-1.32), in comparison to the two intermediate quartiles. In addition, the lowest Ta quartile was associated with significantly higher risk of SGA (OR = 1.18, 95%CI 1.09-1.28) while the highest quartile was associated with significantly lower risk of SGA (OR = 0.91, 95%CI 0.85-0.99). When examining associations among tLBW, SGA and trimester-specific Ta exposures, we found decreased risk of SGA with high Ta quartile during the 1st trimester (OR = 0.82, 95%CI 0.73-0.92), and increased risk for SGA with low Ta quartile during the 3rd trimester (OR = 1.17, 95%CI 1.05-1.31), while all other associations were not statistically significant. Conclusion: Ta is negatively associated with SGA in singleton term births, with increased risk in low Ta and decreased risk in high Ta.

## **P02.0120. From Prey to Hunter: Training Park Workers to Carry Out Tick Collection as an Alternative Approach for Lyme Disease Vector Surveillance**

Karl Forest Berard

*Karl Forest Berard<sup>1</sup>, Alejandra Irace Cima<sup>1</sup>, Karine Thivierge<sup>2</sup>, Sandie Briand<sup>1</sup>, François Milord<sup>1</sup>, Patrick Leighton<sup>3</sup>, Robbin Lindsay<sup>4</sup>, Ariane Adam-Poupart<sup>1</sup>*

- 2. Laboratoire de santé publique du Québec, Montreal, QC, Canada.*
- 3. Faculté de médecine vétérinaire, Université de Montreal, St-Hyacinthe, QC, Canada.*
- 4. National Microbiology Laboratory, Winnipeg, QC, Canada.*

**Abstract:** CONTEXT Lyme disease (LD) has become a major public health concern in Canada, with flannel-dragging being the gold-standard approach for active tick surveillance. Limited resources hinders proper deployment of this surveillance in Quebec, prompting the exploration of alternatives. A participatory project was therefore developed to explore a new tick sampling scheme based on training of park workers. This training was first implemented in fall 2017 and is also scheduled for spring 2018. **OBJECTIVES** Develop and validate a training targeting park employees to (1) allow them to carry out tick sampling activities autonomously and (2) inform them about LD prevention. **INTERVENTION** Training session was developed using governmental material. It combined a theoretical lecture covering basic concepts of LD and a practical segment in which workers carried out a first tick sampling under trainer's supervision. Subsequently, participants were asked to carry an unsupervised sampling at the same location but on a different day. Ticks collected during samplings were identified and screened for pathogens. Evaluation of the training was done by phone interviews with park managers. **OUTCOME** In fall 2017, 64 workers were trained in 8 parks located in health regions with known LD endemic areas (Monteregie, Mauricie-Centre-du-Quebec, Estrie and Outaouais). All parks were sampled once during the training and half of them managed to carry independent samplings. Overall, 38 LD ticks vector were collected. High appreciation of the training and increased awareness of LD risk among workers were highlighted following evaluation **CONCLUSION** An innovative tick collection method involving workers was explored and will be validated in spring 2018. Such approach could potentially improve active tick surveillance activities while promoting occupational preventive measures. Similar initiatives could be implemented on a larger scale in the future to enhance LD surveillance in Canada.

**P02.0130. Short-Term Prediction of Extremely Hot Days and Heat-Related Mortality Due to Enso and Climate Change**

Chu-Chih Chen

*Chu-Chih Chen*<sup>1</sup>

*1. Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan.*

Abstract: The trend of extremely hot temperature days in Taiwan has been increasing during the last decade under climate change. In addition, the associations between the El Niño-Southern Oscillation (ENSO) and temperature and precipitation is well-documented. In this study, based on the observed meteorological data from 1951 to 2016, the estimated climate change trend, and the association with lagged Nino3.4 index, we developed a state-space model for prediction of the extremely hot days in summer for the next few years in Taiwan. We then applied the established model to project heat-related attributable mortality (AM) relative to the reference period 2001-2010. The results showed that the prediction model performed well with high precision. The Taipei metropolitan area is expected to have the most impact with the highest AMs in the near future, which warrants further risk assessment and management for heat-related mortality.

Abstract: Previous research reports associations between ambient air pollution measured during pregnancy and the occurrence of congenital heart defects (CHD) in offspring. The objective of this research was to determine if extreme heat events (EHE) during pregnancy may modify the effect of fine particulate matter (PM<sub>2.5</sub>) on CHD occurrence. The study population consisted of 4074 controls and 2632 CHD cases with dates of delivery between 1997 and 2006 that participated in the National Birth Defects Prevention Study, a large, multi-site case-control study. Using the EPA's Air Quality System, daily data from the closest stationary PM<sub>2.5</sub> monitor within 50km from the maternal residential location were averaged across weeks 3-8 post-conception. Using data from the closest weather monitor, the presence of an EHE was defined as maximum ambient temperature in the upper 95th centile for at least two consecutive days. Interaction between PM<sub>2.5</sub> exposure and EHE was assessed using logistic regression models adjusted for maternal age, ethnicity, education and average humidity. Relative excess risks due to interaction were calculated. Using women with low PM<sub>2.5</sub> exposure and no EHE as the referent, there was some evidence of a stronger relationship between high PM<sub>2.5</sub> and ventricular septal defects among women who experienced an EHE (odds ratio, OR 2.14 95% confidence interval, CI 1.19, 3.38) compared to women who did not experience an EHE (OR 0.97 95%CI 0.49, 1.95); however an opposite association between higher PM<sub>2.5</sub> and right ventricular outflow tract obstruction defects was observed among women who also experienced an EHE (OR 0.68 95%CI 0.36, 1.30). Stratified analyses suggest that the relationships between EHE, PM<sub>2.5</sub> and CHD occurrence are stronger among women whose early pregnancies occur during warmer seasons and in warmer climate regions. This study did not provide substantial evidence of interaction between prenatal exposure to EHE and PM<sub>2.5</sub> and CHD occurrence in offspring.

## **P02.0170. The Co-Impacts of Climate Change Policies on Air Quality - Impacts on Health**

Heather Walton

*Heather Walton<sup>2</sup>, David Dajnak<sup>1</sup>, Nutthida Kitwiroon<sup>1</sup>, Sean D. Beevers<sup>1</sup>, Daniela Fecht<sup>3</sup>, Mireille B. Toledano<sup>3</sup>, Melissa C. Lott<sup>4</sup>, Stephen Pye<sup>4</sup>, Martin L. Williams<sup>1</sup>*

- 1. Environmental Research Group, King's College London, London, United Kingdom.*
- 2. NIHR Health Protection Research Unit on Health Impacts of Environmental Hazards, King's College, London, London, United Kingdom.*
- 3. MRC-PHE Centre for Environment and Health, Imperial College, London, London, United Kingdom.*
- 4. University College, London, London, United Kingdom.*

Abstract: The UK's 2008 Climate Change Act requires an 80% reduction in CO<sub>2</sub>-equivalent emissions by 2050, relative to 1990. Air pollution-associated impacts on health were derived for two policy scenarios (NRPO (nuclear replacement only) and LGHG (low greenhouse gas, with expansion of nuclear power) to meet this reduction, compared with policies in place up to/including the UK 4th carbon budget (the baseline). The energy systems model UK TIMES was linked with air quality model CMAQ-Urban at a 10km rural/2km urban scale to produce annual mean concentrations weighted by ward population (average 6,500 people) for 2011, 2035 and 2050, with linear extrapolation between 2011/2035 and 2035/2050. These concentrations were combined with local authority mortality rates (with birth and mortality improvement projections) and concentration-response functions recommended by the UK Committee on the Medical Effects of Air Pollutants (PM<sub>2.5</sub>, NO<sub>2</sub>) or WHO (ozone). Life years lost were calculated from 2011 to 2154 for Great Britain. Increases in biomass exposures up to 2035 meant that the LGHG and NRPO scenarios resulted in 472,000 and 1,122,000 life years lost from long-term exposure to anthropogenic PM<sub>2.5</sub> compared with the baseline. Reduced NO<sub>2</sub> led to life-years saved (4,892,000 to 7,178,000) rather than lost (range from NRPO, 5 µg/m<sup>3</sup> cut-off to LGHG, 0 µg/m<sup>3</sup> cut-off). However, due to the uncertainty over how much of the effects are due to NO<sub>2</sub> itself rather than other pollutants, the decrease in NO<sub>2</sub> does not eliminate concerns over the PM<sub>2.5</sub> increase from biomass and non-tailpipe emissions. Long-term ozone exposure is projected to decrease but gains are smaller (around 230,000 life years gained) due to the WHO threshold of 35 ppb and the effect on respiratory, not all cause mortality. The opposing trends in NO<sub>2</sub> and PM<sub>2.5</sub> over time may help distinguish pollutant impacts in future epidemiological studies. Careful policy design is needed to optimise greenhouse gas and air pollutant reductions.

## **P02.0180. The Geographic Distribution of Future Ozone-Related Asthma Exacerbation Emergency Department Visits in the Us in a Warming Climate**

Nicholas Nassikas

**Abstract:** Introduction Asthma affects >24 million children and adults in the United States (US). Daily fluctuations in ground level ozone are associated with higher rates of emergency department (ED) visits for asthma exacerbations. For a given level of anthropogenic emissions of ozone precursors, ozone levels are expected to increase by mid-century due to climate change, with a greater increase under a higher versus a lower climate change scenario. We aimed to quantify the magnitude and spatial distribution of asthma ED visits potentially averted mid-century under a mitigation (RCP4.5) versus a business as usual (RCP8.5) greenhouse gas emissions scenario. Methods We projected daily 8-hr maximum ozone levels across the contiguous US for 2036-2055 under two Representative Concentration Pathways (RCP4.5 and RCP8.5) using a 2040 emissions inventory and regional climate and chemical transport models. We then used BenMAP to estimate mid-century ozone-related asthma ED visits for all ages under each RCP, assuming constant population and no adaptation compared to the present. Results Ozone levels are projected to be an average of 1.3 ppb lower across the US under RCP4.5 versus RCP8.5, with the largest differences projected for the Northern Plains, Midwest, and Northeast. Nationally, 2,809 fewer ozone-related ED visits per year mid-century (out of 91,431 total ozone-related ED visits under RCP8.5) are projected under RCP4.5 versus RCP8.5, all other factors held constant. The largest differences (greatest potential benefits under RCP4.5) in asthma-related ED visits are projected for the Northeast and Midwest regions, including Chicago, New York City, Cleveland, Detroit, and Philadelphia. Conclusions These results suggest that adhering to the lower greenhouse gas emissions described by RCP4.5 would lead to lower daily ozone levels and substantially fewer ED visits for asthma across the US, with potential health benefits considerably larger for some communities and individuals than others.

**P02.0190. High Temperature Associations with Preterm Birth and Mediation by Air Pollutants in Detroit, Michigan, 1991-2001.**

**Abstract:** Introduction: Preterm births (PTBs) cause significant infant health risks, and several studies have found associations between high temperatures and PTB. To understand this association in Detroit, Michigan and the extent to which temperature effects are mediated by air pollution, we evaluated both the total and natural direct effects (independent of particulate matter, ozone, and nitrogen dioxide) of two-day mean apparent temperature (AT) on PTB for the warm months (May to September), 1991-2001. We evaluated effect modification by maternal age, race, education, smoking status, and prenatal care. Methods: We used a time-stratified case-crossover design with splines of AT and wind speed (National Center for Environmental Information), solar radiation (National Renewable Energy Laboratory), and citywide average precipitation (Oregon State University's Parameter-elevation Regression on Independent Slopes Model) to estimate total effects. To accommodate multiple mediators and exposure-mediator interactions, AT inverse odds weights, predicted by meteorological and air pollutant (Environmental Protection Agency AirData) covariates, were included in a subsequent case-crossover model to estimate direct effects. Results: At 24.9 deg. C (95th percentile of warm-season AT) vs. 18.6 deg. C (50th percentile of warm-season AT), 18.7% (95% CI: 1.3%, 31.4%) of PTBs were attributable to the total effects of AT and 11.1% (95% CI: 3.5%, 17.5%) to direct effects. Relative excess risks of interaction were null for each potential modifier. Conclusion: This additional evidence of a direct association between high temperature and PTB motivates public health interventions to reduce extreme heat exposures among pregnant women.

## **P02.0200. Grassland Phenology and Meteorology Co-Influence Grass Pollen Counts in Victoria, Australia**

Ha Nguyen

*Ha T. Nguyen<sup>1</sup>, Xuanlong Ma<sup>2</sup>, Ed Newbigin<sup>3</sup>, Paul Beggs<sup>4</sup>, Janet Davies<sup>5</sup>, Alfredo Huete<sup>1</sup>*

*5. Faculty of Health, Queensland University of Technology, Brisbane, QLD, Australia.*

**Abstract:** AIM This study investigated the role of grassland phenology in driving daily and seasonal pollen counts in Melbourne, Victoria and characterized the ecological conditions leading up to Melbourne's epidemic thunderstorm asthma event on 21/11/2016. Landscape ecological conditions have traditionally been overlooked as an environmental driver of pollen variability. An understanding of relationships of pollen counts with vegetation type and phenology is valuable to develop better tools to forecast the pollen season and the associated allergenic risks. **METHOD** We combined 2000-2016 Enhanced Vegetation Index (EVI) data from the Moderate Resolution Imaging Spectroradiometer (MODIS), gridded meteorology products and 1991-2016 grass pollen counts to assess spatial and temporal correspondences among phenology, meteorology and pollen counts in Victoria. Grassland and pollen phenological metrics were analysed for trends and anomalies, and comparisons made of correlations between pollen season metrics and meteorological variables and between pollen season metrics and phenology metrics. **RESULTS** Seasonal grass pollen highly correlated with the integrated EVI while daily grass pollen highly correlated with meteorology. We detected a broad hotspot area northwest of Melbourne which experienced both anomalously high EVI values and a significant delay of peak EVI date in 2016. > 20% of the landscape had not reached peak EVI by the start of the pollen season (05/10/2016), heightening exposure to local flowering and hence pollen emission. **CONCLUSION** We showed that grass phenology directly controls pollen production, including pollen hotspots, whereas meteorology determines where and when high pollen deposition will occur. Future forecasting of pollen season and the associated allergenic risks should take into account the timing and spatial variability of grassland phenology as well as the co-influences over pollen production, transport and deposition between vegetation and meteorology.

## **P02.0210. Relationship between Temperature and Ischemic Heart Disease in Bogotá 2009 - 2014**

Jeimy Corredor Gutiérrez

*3. School of medicine, Universidad de los Andes, Bogotá, Bogotá, Colombia.*

**Abstract:** Temperature changes has been associated with a variety of cardiovascular, respiratory and neurological effects. Evidence that accounts for health effects of temperature in tropical countries as Colombia is scarce. Temperature in Bogota has risen from 1 to 2°C since 1997 and the adverse health effects of such changes are uncertain. In this ecological time series analysis study, we explored the temporal patterns of emergency room daily admissions of ischemic heart diseases (IHD) in relation to temperature, relative humidity, ground level ozone and particulate matter (PM10 and PM2.5) from 2009 to 2014 in Bogota. Statistical analysis included Spearman rank correlation, Poisson regression models and distributed lag non-linear models (DNLM). Admissions for angina pectoris increased by 4.1% for each 1°C rise in maximum temperature; admissions for myocardial infarction dropped by 15.7% as average temperature increased in 1°C and decreased by 2.5% for each unit increase in relative humidity. Regarding DNLM models, the relationship between IHD and temperature was stronger and evident at lower (8 and 11°C) and higher temperatures ( $\geq 19^\circ\text{C}$ ); the effects were mostly immediate, particularly with minimum temperature, but there were some delayed effects with maximum temperature which reached a peak in lags 2 and 3 when was adjusted by PM10 and PM2.5. A significant association was also found between the number of events and a wide thermal variation ( $\geq 12^\circ\text{C}$ ) on the same day. This study is the first approach on the patterns of IHD morbidity because of temperature changes in Bogota, a high-altitude low-latitude city. These findings suggest a non-linear exposure response curve between temperature and IHD. Higher temperatures were associated with angina while lower one were to myocardial infarction. Thermal amplitude and effect modification by PM10 and RH were also factors that triggered the number of daily admissions of IHD. Further studies should assess those findings at individual level.

## **P02.0220. The Influence of Weather on the Health and Welfare Conditions of Pigs in the UK: A Time-Series Analysis**

Shakoor Hajat

*Hyun Ju Lee<sup>1</sup>, Shakoor Hajat<sup>1</sup>, Mary Friel<sup>2</sup>, Richard P Smith<sup>3</sup>, Chloe Perkins<sup>1</sup>, Susanna Williamson<sup>3</sup>, Phil Edwards<sup>1</sup>, Lisa Collins<sup>2</sup>*

*2. University of Leeds, Leeds, United Kingdom.*

*3. Animal and Plant Health Agency, London, United Kingdom.*

Abstract: Given the seasonal nature of some health and welfare conditions in livestock, we explored the extent to which weather factors explain these patterns and whether there are parallels with human health. We obtained the health and welfare data from Food Safety Agency and UK weather data from MET Office. The following conditions were considered: pleurisy, pericarditis, tail biting, TB-like legions and respiratory diseases. Time-series of the daily prevalence of each outcome for the period 2009-2015 were assessed graphically and in relation to daily ambient temperature, adjusting for seasonal patterns, trends and day-of-week effects. The metric considered was daily maximum temperature lagged by up to 28 days. Analyses were conducted at both the national and county-level. The apparent cold effects of the daily maximum temperature on the prevalence of all conditions disappeared after adjustment, particularly for respiratory conditions; there was a 0.6 times decrease in the prevalence of respiratory conditions for every 1°C increase in temperature below 10 °C in the crude model (95%CI 0.57, 0.64). However, in the final model, there was a 1.01 times increase in the prevalence of respiratory conditions for both every 1°C increase in temperature above the lowest value and every 1°C drop below (95%CI 0.86, 1.18; 95%CI 0.88, 1.15 respectively). There was no clear evidence of an association between changes in daily maximum temperature and prevalence of health and welfare conditions. This may be because daily prevalence was not based on the onset of a disease, but rather on the diagnosis of diseases. Although we could not find an association with temperature, other weather factors-rainfall, relative humidity and air frost-may be associated with the prevalence of diseases. Therefore, we will link them with health and welfare data. We are also performing similar investigations using Animal and Plant Health Agency's dataset and the results will be shared.

## **P02.0230. Using Natural Experiments to Evaluate the Potential Public Health Benefits of the Toronto Cold Weather Program**

*2. Public Health Ontario, Toronto, ON, Canada.*

*3. Meteorological Service of Canada, ECCC, Dartmouth, NS, Canada.*

**Abstract:** Extreme cold weather alert programs have been implemented in some areas to address the significant health impacts of exposure to cold. One such program is the Toronto Cold Weather Program (TCWP) that was implemented in the City of Toronto since 1996 to protect the public from extreme weather conditions. In this paper, we aim to evaluate the effectiveness of the TCWP in reducing mortality and morbidity outcomes related to cold temperatures. We applied a quasi-experimental study design using the Difference-in-Differences method coupled with propensity-score-matching to determine the effect of the TCWP on daily hospitalizations and deaths due to cardiovascular disease (CVD), coronary heart disease (CHD) or cerebrovascular disease, using two complementary analytical approaches. Overall, the analysis did not detect an impact on reduced mortality/morbidity in the City of Toronto from the TCWP. For example, we obtained a Risk Difference (RD) of -0.88 (per 1,000,000 people) (95% CI: -3.27 to 1.51) and a Risk Ratio (RR) of 0.98 (95% CI: 0.91 to 1.05) people for CVD hospitalizations. The TCWP was not found to be effective in reducing cold related mortality and morbidity which demonstrates the importance of improving existing policies related to cold in Canada and other countries.

## **P02.0240. Diurnal Temperature Range and Mortality in Tabriz (the Northwest of Iran)**

Narges Khanjani

*Narges Khanjani<sup>1</sup>, Rahim Sharafkhani<sup>1</sup>, Bahram Bakhtiari<sup>2</sup>, Younes Jahani<sup>1</sup>, Jafar Sadegh Tabrizi<sup>3</sup>*

*3. Health Services Management Research Center, Faculty of Management and Medical Informatics, Tabriz University of Medical Sciences, Kerman, KERMAN, Iran (the Islamic Republic of).*

**Abstract:** Introduction: Recently there has been a lot of interest in global warming and temperature variation's effect on health. This study evaluates the impact of Diurnal Temperature Range (DTR) on mortality in Tabriz, northwest of Iran. Methods: Distributed Lag Non-linear Models combined with a quasi-Poisson regression were used to assess the impact of DTR on cause, age and gender specific mortality, controlled for potential confounders such as long-term trend of daily mortality, day of week effect, holidays, mean temperature, humidity, wind speed and air pollutants. As the effect of DTR may vary between the hot season (from May to October) and cold season (from November to April of the next year), we conducted analyses separately for these two seasons. Results: In high DTR values (all percentiles), the Cumulative Relative Risk (CRR) of Non-Accidental Death, Respiratory Death and Cardiovascular Death increased in the cold season. In all seasons and high DTR value (percentile 90), the CRR (lag 0-6) of respiratory deaths increased as well. Conclusion: Although there was no clear significant effect in low DTR values, high values of DTR increase the risk of mortality in the cold season, in Tabriz, Iran.

## **P02.0250. Climate Change Impact on Heat-Related Mortality - ISI-MIP Context**

Yasushi Honda

*Yasushi Honda*<sup>1</sup>

*1. Faculty of Health and Sport Sciences, University of Tsukuba, Tsukuba, Ibaraki, Japan.*

**Abstract:** Background The Inter-Sectoral Impact Model Intercomparison Project (= ISI-MIP) describes itself as "a community-driven climate-impacts modelling initiative aimed at contributing to a quantitative and cross-sectoral synthesis of the differential impacts of climate change." In the project, we compared the difference in number of heat-related deaths among some scenarios including 1.5 degree target. Methods If Representative Concentration Pathway (= RCP) 2.6 is assumed, 1.5 degrees warmer than the preindustrial level would be projected by global circulation models (=GCMs) GFDL-ESM2M, HadGEM2-ES and MIROC5. For these projections, we conducted the future heat-related mortality projections using Shared Socioeconomic Pathways (= SSPs) 1 and 3. As for the calculation of heat-related deaths, we used the model by Honda et al (2014), in which higher risk than minimum mortality temperature (=MMT) at higher than MMT was used. Results Under RCP2.6, SSP1 scenario, number of heat-related deaths in the world estimated with GFDL-ESM2M for 1991-2000 (baseline) and that for 2091-2099 was 143,178 and 381,795. With MIROC5, the numbers were 124,826 and 448,607. At the end of the century, the number of deaths became 2.7 times with GFDL-ESM2M and 3.6 times with MIROC5 compared with the baseline. Under RCP6.0, SSP1 scenario, the corresponding numbers for 2091-2099 were 743,200 with GFDL-ESM2M and 812,612 with MIROC5. Because RCP2.6 and SSP3 cannot coexist, here we report the RCP6.0, SSP3 for 2091-2099. It was 1,248,275 with GFDL-ESM2M, and 1,363,703 with MIROC5. Discussion the heat-related mortality is much more serious in case of SSP3 than in case of SSP1. Under SSP1, the difference between RCP6.0 and RCP2.6 seems also large. The GCM model difference was much smaller than the difference in SSP or RCP. Acknowledgment This study was supported by the Environmental Research and Technology Development Fund (S-14) of the Environmental Restoration and Conservation Agency, Japan.

## **P02.0270. Associations of Temperature Variation and Mortality in 47 Japanese Prefectures**

Chaochen Ma

*Chaochen Ma<sup>1</sup>, Daisuke Onozuka<sup>1</sup>, Yasushi Honda<sup>2</sup>*

*1. Department of Health Communication, Kyushu University, Fukuoka, Fukuoka, Japan.*

*2. Faculty of Health and Sport Sciences, University of Tsukuba, Tsukuba, Ibaraki, Japan.*

**Abstract:** Background / Aim: Few studies have investigated the mortality effects of temperature variation (TV) in Japan. In this study, we employed the newly proposed indicators of inter- and intra-day TVs computed separately using daily mean temperatures above or below the minimum mortality temperature to assess the TV-mortality associations and their relative contribution in comparison to daily mean temperature across Japan. Methods: We collected daily data on temperature and mortality during 1972-2012 from 47 Japanese prefectures. We performed a quasi-Poisson regression analysis incorporating a distributed-lag non-linear model to estimate associations of daily mean temperature, inter- and intra-day TVs with mortality in each prefecture. Results: Most prefectures showed a significant increase in mortality risk associated with daily mean temperature, with relative risks (RRs) reaching 1.236 (95% confidence interval (CI): 1.163, 1.313) for heat in Aomori, and 1.676 (95% CI: 1.313, 2.138) for cold in Wakayama. Inconsistent results for inter- / intra-day TVs were found, except for some protective associations between intra-day TV and mortality in Kochi (RR 0.979; 95% CI: 0.965, 0.993) and Gifu (RR 0.988; 95% CI: 0.98, 0.996) on cold days. Conclusion: We found that the association between mortality and TV was generally small compared with daily mean temperature in Japan. Acknowledgement: this research was supported by the Environmental Research and Technology Development Fund (S-10 & S-14) of the Ministry of the Environment, Japan.

## **P02.0280. Examining the Association between Temperature and Emergency Room Visits from Mental Health-Related Outcomes in California**

Rupa Basu

*2. Yale University, New Haven, CT, United States.*

**Abstract:** Temperature and morbidity has been explored previously. However, the association between temperature and mental health-related outcomes, including violence and self-harm, remains relatively unexamined. We obtained daily counts of mental health-related emergency room visits involving injuries with external cause from the California Office of Statewide Health Planning and Development from 16 California climate zones from 2005 to 2013, and combined them with data on mean apparent temperature, a combination of temperature and humidity. Using Poisson regression models, we estimated climate zone-level associations, then used random-effects meta-analyses to produce overall estimates. Analyses were stratified by season (warm: May-October; cold: November-April), race/ethnicity, and age. A 10-degree Fahrenheit increase in same-day mean apparent temperature was associated with a 4.8% (95% confidence interval, 3.6-6.0%), 5.8% (4.5-7.1%), and 7.9% (7.3-8.4%) increase in visits for mental health disorders, self-injury/suicide, and intentional injury/homicide, respectively, during the warm season. High temperatures during the cold season were also positively associated with these outcomes. Variations were observed by race/ethnicity, age group, and sex, with Hispanics, Whites, 6-18 year olds, and females at greatest risk for most outcomes. Increasing mean apparent temperature was found to have acute associations with mental health outcomes and intentional injuries, and warrants further studies in other locations.

## **P02.0300. Assessing United States County-Level Exposure for Hurricane and Tropical Storm Epidemiological Research**

**Abstract:** Hurricanes and other tropical storms bring severe impacts to U.S. communities. These impacts can result from a variety of storm-related hazards, including extreme wind, rain, flooding, and tornadoes. Epidemiological studies vary widely in how they classify exposure to tropical storms, using various hazard-based metrics and, in some cases, using distance from the storm as a surrogate for exposure to storm-related hazards. Here we measure county-level exposure to hurricanes and tropical storms in the United States based on distance from the storm, maximum sustained wind, rainfall, flooding, and tornadoes for all land-falling or near-passing Atlantic basin storms for 1988--2015. We show that the locations identified as storm-exposed varied substantially when switching among these metrics. For example, most wind-based storm exposures were limited to southern counties near the coast, while flood- and rain-based exposures often extended to inland and northern counties. We also show that distance to the storm served as at best a moderate, and often a poor, surrogate in identifying exposure to storm-related wind, rain, floods, or tornadoes. Therefore, when impact studies use distance as a surrogate of exposure to tropical storm exposures or use one hazard-based metric (e.g., wind-based) when the impact is partly or fully caused by a different storm hazard, the analysis will be prone to exposure misclassification, which can mask true associations, even strong associations. To facilitate future research, we make this multi-hazard storm exposure data available through open-source software.

**P02.0310. Trends of Age-Specific Mortality with an Underlying or Contributing Cause Attributed to a Weather-Related Cause of Death in Japan, 1995-2015**

Masao Kanamori

*Masao Kanamori<sup>1</sup>, Fumiko Tsukuda<sup>1</sup>, Aya Hayashi<sup>1</sup>, Seiichi Nakai<sup>1</sup>, Yasushi Honda<sup>2</sup>*

*2. School of Health and Physical Education, University of Tsukuba, Tsukuba, Ibaragi-ken, Japan.*

**Abstract:** Objective: To observe the effect of climate change on the mortality of the elderly and children, we examine age-specific heat-related(HM) and cold-related mortality(CM), and other weather-related mortality during 1995-2015 in Japan. Method: Deaths with an underlying or contributing cause attributed to a weather-related cause of death were included. Heat-related death certificate of ICD-10 codes X30 (exposure to excessive natural heat), T67(heatstroke or sunstroke), cold-related deaths X31(exposure to excessive natural cold), T68(hypothermia), flood-storm-lightning-related deaths. Odds ratios(OR) for weather-related deaths by sex, age group, and period group were obtained using logistic regression. Results and Conclusion: About 93,000 Japanese died from weather-related cause of death (0.41 percent of total death) during 1995-2015. CM tended to have a higher mortality than HM. The tendency was remarkable in male. OR of gender difference between HM and CM is 1.30(1.25-1.35). Based on the mortality at the age group of 40-45 years, the risk of heat-related death increased with aging and increased significantly over aged 80-84(OR 16.9 in X30). CM tended to be similar to HM, and no difference was observed. As a result of analysis in the summer weather in two groups of hot and warm summer, the effect on the mortality of hot weather of elderly people over 80 years old was remarkable as the increase of HM (OR 2.71). There was a tendency that the decrease of CM was lower in the hot summer. For children, HM increased by 2.94 times (aged 10-14, 2003), 2.31 times (aged 15-19, 2011) in the hot summer, but the increase in mortality did not show a certain trend. The differentials in weather-related mortality observed among older people over 80 years old were consistent with previous studies. This study made it possible to better understand the trend of weather-related mortality by observing age-specific mortality. This work was supported by JSPS KAKENHI Grant Number JP17K01829.

## **P02.0320. Impact of Meteorological Parameters on Suicide Rates: A Case-Crossover Study in Southern Germany**

Alexandra Schneider

*Alexandra E. Schneider<sup>1</sup>, Regina Hampel<sup>1</sup>, Karl-Heinz Ladwig<sup>1</sup>, Jens Baumert<sup>2</sup>, Karoline Lukaschek<sup>1</sup>, Annette Peters<sup>1</sup>, Susanne Breitner<sup>1</sup>*

*1. Institute of Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany.*

*2. Department of Epidemiology and Health Monitoring, Robert Koch Institute, Berlin, Germany.*

**Abstract:** Background. Researchers worldwide reported a seasonal pattern of suicides with peaks in spring and early summer; however, only a limited number of studies has investigated the association of meteorological variables and suicides. Methods. Daily suicides (N=10,595) and meteorological data from 1990 to 2006 were available for four Bavarian cities and ten counties. Immediate, delayed and cumulative effects of air temperature, sunshine duration, cloud cover, relative humidity as well as precipitation on suicide rates were analyzed using a confounder-adjusted time-stratified case-crossover approach. Potential effect modifiers were specific weather conditions, personal or regional characteristics, and season. Results. A 5°C increase in air temperature was associated with a 4.1% (95%-confidence interval: 0.97; 7.4%) and 5.1% (2.0; 8.4%) higher suicide risk on the same day and with a delay of one day, respectively. Further, the suicide risk was 6.2% (0.6; 12.2%) higher on days with low/medium cloud cover (0-6 oktas) compared to days with high cloud cover (7-8 oktas). Temperature effects with a lag of one day were more pronounced in individuals older than 65 years (9.9% (4.3; 15.8%)). While temperature was not associated with suicides in spring we found positive associations in summer, autumn, and winter. The effects of cloud cover were strongest in summer and autumn and on days with air temperature above the median (>8.8°C). The other meteorological variables were not significantly associated with suicide. Discussion. We found a higher risk for suicides in association with short-term increases in air temperature and on days with low to medium cloud cover. This may highlight time periods when people are more likely to commit suicide.

## **P02.0330. Establishing Appropriate Hot Weather Alerting Criteria for British Columbia, Canada**

Kathleen McLean

*Kathleen E. McLean<sup>1</sup>, Melissa MacDonald<sup>2</sup>, Sarah B. Henderson<sup>1</sup>*

- 1. Environmental Health Services, BC Centre for Disease Control, Vancouver, BC, Canada.*
- 2. Meteorological Service of Canada, Environment and Climate Change Canada, Dartmouth, NS, Canada.*

**Abstract:** A heat health warning system (HHWS) was developed for the greater Vancouver area of British Columbia (BC), Canada following an unprecedented extreme hot weather event that resulted in a 40% increase in weekly mortality. While the greater Vancouver HHWS has been operational since 2012, there are currently no HHWSs covering the remainder of the province. In collaboration with Environment and Climate Change Canada we established hot weather alerting criteria for four regions with broadly similar climates in BC. We used daily forecasted and observed minimum and maximum air temperatures and daily mortality counts for May through September during 2004 to 2016. For each date (dayt), we selected daytime forecast high temperatures for dayt and dayt+1 and the overnight forecast low temperature falling between dayt and dayt+1 from forecasts made in the afternoon of dayt-2. We tried a range of combinations of minimum and maximum temperature thresholds for each of four climatic areas. For each date, we assigned a hot weather warning category equal to the sum of the total degrees by which the daytime forecast highs fell under the maximum threshold and the overnight forecast low fell under the minimum threshold. We assessed associations between the categories and daily mortality using time-series models. We established the following minimum/maximum hot weather alerting criteria, to be adopted in the summer of 2018: 16°C/29°C in the Southwest; 18°C/35°C in the Southeast; 13°C/28°C in the Northwest; and 14°C/29°C in the Northeast. These values were established by balancing a number of considerations regarding the appropriateness of each threshold, including evidence-based associations with daily mortality and minimization of warning fatigue. These criteria identified the two province-wide extreme hot weather events that affected BC in 2009 and 2015. Hot weather alerting criteria covering all of BC can help public health authorities and citizens prepare for extreme hot weather events.

**P02.0340. Comparison of Two Wet-Bulb Globe Temperature Estimation Methods for Assessment of Heat-Related Mortality: Evidence from 47 Japanese Prefectures**

Chaochen Ma

*2. Faculty of Health and Sport Sciences, University of Tsukuba, Tsukuba, Ibaraki, Japan.*

**Abstract:** Background / Aim: The wet-bulb globe temperature (WBGT) has been widely used for the heat warning in Japan. However, since the WBGT instruments are not often readily available, it needs to be estimated from the measurements of the common meteorological variables. In this study, we tested the reliability of the WBGT estimation method used by the Australian Bureau of Meteorology (ABM) by comparing it with a proven accurate estimation method by Ono et al. (2014) for evaluating the heat-mortality associations in Japan. Methods: We collected daily data on temperature, humidity, solar radiation, wind speed, water vapor pressure and all-cause mortality from 47 Japanese prefectures during 2006-2012. The meteorological data we used were the daily average ones. The data were restricted to the warm season (May-October). After deriving the WBGT estimates by using each method respectively, a quasi-Poisson model combined with a distributed lag nonlinear model (DLNM) was applied to estimate the WBGT-mortality associations in each prefecture. Results: The correlation coefficient between the two types of WBGT estimates was around 0.95. The estimates of minimum mortality WBGT (MMW) and minimum mortality WBGT percentile (MMWP) by using two WBGT estimates were very inconsistent across prefectures. The correlation coefficient between two sets of MMWs was only 0.3. Conclusions: We found that the WBGT estimates provided by the ABM's method is not accurate enough to express the heat-mortality associations. That may be due to its assumption of the fixed solar radiation and wind speed. Acknowledgement: This research was supported by the Environmental Research and Technology Development Fund (S-10 & S-14) of the Environmental Restoration and Conservation Agency, Japan.

## **P02.0350. The Effect of High Summer Temperatures on Emergency Hospital Admissions in Switzerland: A Comparison to Heat-Related Mortality**

Martina Ragettli

*Martina S. Ragettli<sup>1</sup>, Ana M. Vicedo-Cabrera<sup>2</sup>, Benjamin Flückiger<sup>1</sup>, Tarik Benmarhnia<sup>3</sup>, Martin Röösli<sup>1</sup>*

*2. Department of Public Health, Environments and Society, London School of Hygiene & Tropical Medicine, London, United Kingdom.*

*3. Department of Family Medicine and Public Health, University of California, San Diego, San Diego, CA, United States.*

**Abstract:** Background. While previous studies showed a clear association between high temperatures and mortality in Switzerland, the effect of heat on morbidity is less well understood. To evaluate how hot weather affects morbidity in Switzerland and how it compares to heat-related mortality, we assessed a) cause-specific morbidity during the hot summer 2015, and b) the relationship between heat and emergency hospital admissions (EHA) between 2006 and 2015. Methods. Daily EHA during the summer 2015 (June-August) were analysed in relation to comparison periods. For aim b) daily relationships between day-time maximum (Tmax) temperature and EHA during the warm season (May-September) 2006 to 2015 were assessed for different diagnoses and age groups by applying conditional Poisson regression models combined with Non-Linear Distributed lag models. Results were compared to our similar analyses on heat-related mortality. Results. Overall, we estimated an increase in EHA (non-external causes) by 2.6% (95%CI: 0.2-5.0) during the summer 2015. For the same period, an excess mortality of 5.4% (3.0-7.9%) was estimated. Between 2006 and 2015 an increase in Tmax from the median (22°C) to the 98th percentile (33°C) was associated with an overall 3% increase in EHA over the following four days (relative risk (RR) of 1.03 (95% CI: 1.02-1.05)). Larger increases were observed for respiratory (1.20 (1.09-1.31)) and renal diseases (1.21 (1.04-1.40)) in people aged  $\geq 74$  years, and for infection-related EHA, mainly in children <15 years old (1.24 (1.11-1.37)). In contrast to heat-related mortality, no significant association between Tmax and cardiovascular EHA was found. Conclusions. Our results indicate that increases in ambient temperature during summer months have important impacts on morbidity. In general, the impact was smaller than what was observed for heat-related mortality. Nevertheless, current public health strategies can greatly be improved when targeting measures to both groups of outcomes.

## **P02.0360. Development of Guide Book on Outpatient Treatment and Physical Checkup for Accident Preparedness Substances**

**Abstract:** INTRODUCTION On September 27, 2012, Hydrogen fluoride leakage accident occurred in Hube Global Co.,Ltd. And such massive chemical accidents involve environmental pollution and severe impact on human bodies. The accidents also may cause large number of victims. Therefore, it is necessary to develop and distribute a guide book on treating outpatient and physical checkup in case of chemical accidents. METHODS For the guide book, certain substances against accidents are selected based on data from Occupational Safety & Health Research Institute and American Center for Disease Control and Prevention, The items correspond to South Korea's status and the related specialists can immediately refer to the guide book on fields or medical institutes in case of chemical accidents. RESULTS The guide book includes information on following items 1) Guide on physical checkup and outpatient treatment for each substances, 2) Guide on first aid, 3) Introductions for physical checkup and outpatient treatment, 4) Substance information sheet for patients, 5) Follow up sheet for patients. CONCLUSIONS This guide book's advantage is that it can be used immediately by related specialist on fields or medical institutes during the chemical accident. In addition, the guide book explains on how to make questionnaire for exposure assessment during the survey on health impact and on how to collect and store biological monitoring sample. Such information will be very useful when dealing with chemical accidents. ACKNOWLEDGEMENT This research was supported by the Environmental Health Center for Hazardous Gas Exposure. Abstract: During the last 15 years, many countries established heat-health watch and warning systems (HHWWS) in order to prevent large amounts of death or hospitalization due to extreme heat. These systems consists in emergency measures launched whenever a heat indicator crosses a predetermined thresholds. Therefore, it is critical to accurately choose the threshold to avoid, either missing important heat events, either triggering too much alerts which would reduce their impact. Because of the usefulness of HHWWS, it is also of interest to extend them to other extreme weather events such as cold spells. However, the methodologies used around the world to set the threshold in the case of heat are highly subjective and do not extend to other weather events or locations. In the present work, we propose objective and data-based methodologies to determine thresholds from a health issue and weather indicators. These methodologies are proposed with the objective of finding a "bump" in the relationship between the health issue and the weather indicators. For this, the machine learning techniques of decision trees and bump hunting are adapted to the case of optimal threshold finding. These methods have the advantage of needing only few subjective decisions from the public health authorities, being efficient with a large number of variables and being flexible enough to be adapted to a large number of variables and locations. Applying them to the common heat-related overmortality case shows that they are able to be more accurate than methods found in the literature to predict overmortality events. These methods are then expected to be useful for improve current thresholds and establish health watch and warning systems for other extreme weather events.

## **P02.0380. Association between Cardiovascular Mortality and Temperature in Mexican Cities**

**Abstract:** Background/Aim Low and high temperatures have been associated with mortality risk. In addition, the temperature-mortality relationship is different across geographic locations and specific causes. The aim of this study was to assess the non-linear and lagged cold and heat effects on cardiovascular mortality in people 65 years old and over from 10 Mexican cities. Methods Average daily temperature and daily counts of mortality were collected from 10 Mexican cities, with more than 1 million inhabitants, from 1998 to 2014. Analyses were carried out through quasi-Poisson regression models with distributed lag non-linear models with 7 days of lag. The association between cold and hot temperatures and mortality was evaluated using cutoffs at 1st and 99th percentiles. The specific estimates were pooled and analyzed by meta-analysis. Models were adjusted for relative humidity, day of the week and holidays. Results Cumulative relative risk (RR) over 7 days (lag 0-7) estimated in conditions of very cold temperatures (under 1st percentile of each metropolitan area) showed the following ranges and pooled effect [RR(95%CI)] for cardiovascular  $RR_{Cav} = 0.89 (0.73, 1.08)$  to  $1.56 (1.19, 2.03)$ ,  $RR_{Pooled} = 1.20 (1.10-1.30)$ ; ischemic heart  $RR_{Isch} = 0.97 (0.75, 1.24)$  to  $3.25 (1.37, 7.72)$ ,  $RR_{Pooled} = 1.32 (1.19-1.48)$ ; cerebrovascular  $RR_{Cev} = 0.67 (0.35, 1.30)$  to  $1.77 (1.27, 2.47)$ ,  $RR_{Pooled} = 1.17 (1.02-1.33)$ . On the other hand, the RR by very hot temperatures (above 99th percentile of each metropolitan area) up to 3 days (lag 0-3) showed the following trend  $RR_{Cav} = 0.70 (0.42, 1.14)$  to  $1.72 (1.33, 2.22)$ ,  $RR_{Pooled} = 1.11 (1.04-1.19)$ ;  $RR_{Isch} = 0.60 (0.33, 1.11)$  to  $1.63 (1.19, 2.24)$ ,  $RR_{Pooled} = 1.12 (1.03-1.23)$ ;  $RR_{Cev} = 0.94 (0.45, 1.97)$  to  $1.36 (0.79, 2.34)$ ,  $RR_{Pooled} = 1.12 (1.08-1.17)$ . Conclusions Our findings suggest that cold and hot temperatures are associated with increased risk mortality for the studied causes in a vulnerable population of 65 years old and over in 10 Mexican cities.

## **P02.0390. Temperature and Fall-Related Hospital Admissions in Hong Kong Sar, China**

Chao Luo

*Chao Luo<sup>1</sup>, William B. Goggins<sup>1</sup>, Emily Chan<sup>1</sup>*

*1. Jockey Club School of Public Health and Primary Care, The Chinese University of Hong Kong, Sha Tin, Hong Kong, Hong Kong.*

**Abstract:** Background/Aim Previous studies have found increased fall incidence during winter months. However, most of the studies were conducted among the elderly only. Few studies have directly examined the impact of weather on the occurrence of falls. The findings of these studies are also not consistent. Therefore, this study aimed to explore the influences of temperatures on falls. Methods Between 1998 and 2011, daily falls-related hospital admission were obtained from Hong Kong Hospital Authority, which were compiled with daily meteorological and air pollutants data obtained from the Hong Kong Observatory and Environmental Protection Department, respectively. Generalized Additive Models were used to estimate the effects of daily mean temperature (°C) on daily falls-related hospital admissions while controlling for other meteorological factors, air pollutants, day of the week, seasonality and long-term trends. Lagged effects were also considered. Results A total of 400,737 fall-related hospital admissions were analyzed. The highest falls incidence rate was observed in January, while the lowest in May. A reverse J-shaped association was found. Below a threshold temperature of 28.5°C, daily mean temperature was significantly negatively associated with fall-related hospital admissions. A daily mean temperature of 19.5°C (25th percentile) and 14.5°C (5th percentile) over lags 0-7 were associated with a 11% higher [95% confidence interval (CI): 1.07, 1.15] and 21% higher [95% CI: 1.15, 1.21] falls risks when compared to 28.5°C, respectively. Conclusions A reverse J-shaped association was found between ambient temperature and falls in the general population in a subtropical Asian city. Since falls are predicted to become the 17th leading cause of death by 2030, it is important to better understand the impacts of the changing climate on falls. Preventive plans such as providing proper heating may help decrease the risk of falls associated with low temperatures.

**P02.0400. Short-Term Association between Ambient Temperature and Mental Disorders Hospitalization in an Asian Subtropical City: A Time-Series Study**

Holly Lam

*Emily Chan<sup>1</sup>, Holly Lam<sup>1</sup>, Suzanne So<sup>1</sup>, William B. Goggins<sup>1</sup>, Janice Y. Ho<sup>1</sup>, Sida Liu<sup>1</sup>, Phoebe Chung<sup>1</sup>*

*1. The Chinese University of Hong Kong, Hong Kong, Hong Kong.*

**Abstract:** Background With the increasing evidence of climate change, human health impact associated with rising global temperature has received more attention. Studies from higher latitudes, with cooler climates, have reported positive temperature-mental disorders association but the association from lower latitudes with warmer climates is still unclear. This study showed the short-term temperature-mental disorders association in a subtropical city located below the Tropic of Cancer with an annual mean temperature over 21°C. Methods Daily mental disorders admissions to public hospitals in Hong Kong during 2002-2011 were regressed on daily mean temperature using distributed lagged nonlinear models with relative humidity, air pollutants, seasonal trend, long term trend, day-of-week and holiday adjusted in the models. Sub-group analyses by disease classes, gender and age-group were conducted. Results A total of 44 600 admissions were included in this study. Temperature was linearly and positively associated with overall mental disorder hospitalizations. The cumulative relative risk of admissions at 28°C vs. 19.4°C (interquartile range, lag 0-2 days) was 1.09 (95% confidence interval 1.03, 1.15). The effect of rising temperature above a threshold of 19°C was the strongest among the elderly > 75 years old. In subgroup analyses by disease classes, episodic mood disorders and transient mental disorders due to conditions classified elsewhere showed strong positive associations with temperature. Conclusions The results of this study agreed with most of those from prior studies that high temperature was associated with a higher risk of mental disorders and the effects were more prominent among older people. The global number of heat-related mental disorder events may grow with the dual effect of global warming and aging population. Health policies should be drafted to address these issues.

## **P02.0420. Estimation of Thermal Comfort Using a WRF-MENEX Model during a Heat Wave in a Complex Urban Area**

Mi-Kyoung Hwang

*Mi-Kyoung Hwang<sup>1</sup>, Inbo Oh<sup>2</sup>, Jin-Hee Bang<sup>2</sup>, Sungmin Kim<sup>3</sup>, Yoo-Keun Kim<sup>1</sup>*

*2. Environmental Health Center, University of Ulsan College of Medicine, Ulsan, Korea (the Republic of).*

*3. Division of Earth Environmental System, Pusan National University, Busan, Korea (the Republic of).*

Abstract: Thermal comfort could indicate human thermal sensation when exposed to a local meteorological condition. Because humans can suffer illness when exposed to heat or even die, it is essential to assess human comfort levels to increased temperature and to provide this information to the public. This study aims to estimate thermal comfort using the human heat balance model combined with a numerical meteorological model in Seoul mega-city during the heat wave periods experienced during 2016. The gridded thermal comfort index, physiological subjective temperature (PST), was calculated based on the Man-Environment heat Exchange (MENEX) model, which used as inputs the meteorological parameters, clothing insulations, and metabolic rates. High-resolution meteorological parameters were obtained by coupling Weather Research and Forecasting (WRF) with Building Effect Parameterization (BEP)/Building Energy Model (BEM) using detailed urban classification. The modeling results showed that the PST distribution has a clearly heterogeneous spatial distribution during the heat-wave period. The high PST values were largely found in the residential area located in the urban center, due to the high temperature and low wind speed associated with high-density buildings, and the daily maximum PST reached a high temperature of over 44 oC. Our study suggested that the human heat balance model combined with the numerical meteorological model could be used to provide more reliable information about thermal comfort to groups that may be vulnerable to the effects of heat waves in complex urban environments. Acknowledgements. This work was supported by Korea Environment Industry & Technology Institute(KEITI) through the Environmental Health Action Program, funded by Korea Ministry of Environment(MOE)(2017001350003)

## **P02.0430. Cold Temperature and Risk of Death Due to Stroke**

Marianne Bilodeau-Bertrand

*Nathalie Auger<sup>1</sup>, Marianne Bilodeau-Bertrand<sup>1</sup>, Audrey Smargiassi<sup>2</sup>, Tom Kosatsky<sup>3</sup>*

*1. University of Montreal Hospital Research Centre, Montreal, QC, Canada.*

*2. School of Public Health, University of Montreal, Montreal, QC, Canada.*

*3. National Collaborating Centre for Environmental Health, British Columbia Centre for Disease Control, Vancouver, BC, Canada.*

**Abstract:** Objective: Temperature is associated with the risk of death due to myocardial infarction, but the relationship with cerebrovascular events is poorly understood. We evaluated the association between cold temperature and the risk of death due to haemorrhagic or ischemic stroke. Methods: Using data from provincial death registration certificates, we undertook a case-crossover study to investigate the association between cold temperature and death due to stroke during 1981-2013 in Quebec, Canada. We selected deaths between November and April, the coldest months of the year, and paired them to the temperature data. Temperature data were obtained from Environment Canada monitoring stations for each of the 18 health regions in Quebec. We used conditional logistic regression to compute odds ratios (OR) and 95% confidence intervals (CI) for the association between minimum daily temperature and haemorrhagic and ischemic stroke. Models were adjusted for the duration and quantity of snowfall. Results: There were 13,208 deaths due to haemorrhagic stroke, and 16,383 due to ischemic stroke during the study. The risk of death from haemorrhagic stroke was elevated on cold days as well as the following day. Compared with 0°C, a minimum temperature of -30°C was associated with an OR of 1.22 (95% CI 1.08-1.38) for haemorrhagic stroke the day of exposure, and an OR of 1.18 (95% CI 1.04-1.33) the day following exposure. Associations were weaker and not statistically significant for ischemic stroke. Conclusion: Cold temperature was associated with risk of death due to haemorrhagic stroke. In the context of climate change and a greater frequency of extreme winter events, individuals with predisposing risk factors should be aware of the higher risk of death due to haemorrhagic stroke during cold temperature. Environmental alerts targeting populations at risk, including recommendations to minimize exposure during extreme cold, may be merited.

## **P02.0431. The Role of Fulbright Program in Focusing on Canadian and U.S. Environmental Health Issues**

David Goldsmith

*David F. Goldsmith<sup>1</sup>*

*1. Human Science, Georgetown University, Silver Spring, MD, United States.*

Abstract: Background: Scholars from Canada and U.S. have collaborated with the Fulbright Program to address environmental issues of mutual interest in both countries. Studies of climate change in the arctic and health of Indians/First Nations illustrate the role of Fulbright investigators have had on these issues. Context: Climate change has had drastic impacts on Arctic communities in Alaska and in northern Canadian villages. Researchers from Canada and U.S., spurred on by Fulbright, have brought investigators together to measure the extent of sea level rise and methods to respond to these changes, including rebuilding indigenous communities away from degraded shores. Scholars from U.S. and Canada have also collaborated on means and methods to address environmental degradation, wildlife habitats, and Indian/First Nation health impacts. Examples include indigenous diets, obesity, and diabetes, adolescent suicide, alcoholism, violence towards women, and childhood accidents. Future collaboration: Canada and U.S. share industrial interests in fishing, agriculture, and mining/petroleum extraction, all of which have high rates of workplace accidents, trauma, and death. Additionally, all three industries have very high indigenous participation and concern. Fulbright programs, including active participation from corporate scientists, can be vehicles for developing innovative transnational initiatives to reduce accident injury and death as well as methods for environmental remediation. We need greater professional interest and applications by environmental scientists to Fulbright as well as new environmental health programs directly sponsored by Fulbright to provide a higher profile for future offerings. Conclusion: The Fulbright program has enabled Canadian and American academics and leaders to collaborate across our borders to tackle serious environmental issues. New problems, such as lowering workplace injury rates, need to be added for future scholars to tackle.

## P02. Built Environment, Noise and Greenness 2

### **P02.0440. Environmental Noise Pollution and Risk of Hypertension in Pregnancy**

Marianne Bilodeau-Bertrand

*Nathalie Auger<sup>1</sup>, Marianne Bilodeau-Bertrand<sup>1</sup>, Audrey Smargiassi<sup>2</sup>*

*1. University of Montreal Hospital Research Centre, Montreal, QC, Canada.*

*2. School of Public Health, University of Montreal, Montreal, QC, Canada.*

**Abstract:** Background: A growing number of studies suggest that environmental noise pollution may impact the risk of hypertension, but the relationship during pregnancy is poorly understood. We investigated the association between environmental noise levels and preeclampsia, a hypertensive disorder of pregnancy. Methods: We undertook a retrospective cohort study of 269,263 pregnancies in Montreal, 2000-2013. Using postal codes, we assigned environmental noise pollution levels (dBA) from land use regression models to each pregnancy. We calculated odds ratios (OR) and 95% confidence intervals (CI) for the association of environmental noise with preeclampsia, adjusted for air pollutants, neighbourhood walkability, maternal age, parity, multiple pregnancy, comorbidity, socioeconomic deprivation, and year of delivery. We assessed if associations varied according to preeclampsia severity (mild and severe) and onset time (<34 and ≥34 weeks of gestation). Results: Women exposed to elevated environmental noise levels (≥65 vs. <50 dBA) had a higher prevalence of preeclampsia (37.9 vs. 27.9 per 1,000). Compared with 50 dBA, exposure to a noise level of 65 dBA was associated with 1.09 times the odds of preeclampsia (95% CI 0.99-1.20). Associations were stronger for severe preeclampsia (OR 1.29, 95% CI 1.09-1.54) and preeclampsia before 34 gestational weeks (OR 1.71, 95% CI 1.20-2.43). There was no association with mild preeclampsia and preeclampsia at ≥34 weeks. Conclusion: Environmental noise pollution may be a risk factor for preeclampsia, particularly severe or early onset preeclampsia. In light of rising levels of urban noise, these results suggest that vulnerable populations, including pregnant women, could benefit from residential noise reduction policies.

## **P02.0450. The Impact of Rural Residence on Depression in the Ginkgo Evaluation of Memory Study**

Erin Semmens

*Erin O. Semmens<sup>1</sup>, Anjum Hajat<sup>2</sup>, Erin Morgan<sup>2</sup>, Annette Fitzpatrick<sup>3</sup>, Joel D. Kaufman<sup>4</sup>*

*1. Public and Community Health Sciences, University of Montana, Missoula, MT, United States.*

*2. Epidemiology, University of Washington, Seattle, WA, United States.*

*3. Family Medicine, University of Washington, Seattle, WA, United States.*

*4. Environmental and Occupational Health Sciences, University of Washington, Seattle, WA, United States.*

**Abstract:** Introduction: Residence in rural environments has been linked to substantial health disparities including elevated incidence of depression. Risks caused by the rural environment may be due to differences in environmental exposures and their demonstrated impacts on the brain, disparities in access to mental health care, and increased poverty. Geocoding challenges, difficulties in environmental exposure assessment, and small, widely dispersed populations are barriers to doing research in rural areas. Nevertheless, it is critical to include these populations, which have been underrepresented in environmental public health research. Methods: More than 3,000 participants 75 years of age and older residing in four communities in the US were followed between 2000-2008 in the Ginkgo Evaluation of Memory Study (GEMS). Rurality was defined by zip code-level Rural-Urban Commuting Area (RUCA) Version 2 codes. The Centers for Epidemiologic Studies - Depression scale was used to assess depression at baseline and twice a year during follow-up. We evaluated the relationship between RUCA code and depression at baseline using linear regression adjusted for sociodemographic factors and study community. Potential modification of the effect of rurality by study community was also examined. Results: Most GEMS participants resided in "metropolitan" areas. Preliminary analyses indicate no overall impact of RUCA code on depression score but that the impact of a one-unit increase in RUCA code was associated with a small but significantly greater increase (0.56; 95% CI: 0.17, 0.96) in depression score in Washington County, Maryland, relative to Pittsburgh, Pennsylvania. Conclusions: Findings suggest that the effect of rurality on prevalent depression varies by community. Future analyses will examine potential interactions of rural residence and environmental exposures and their impact on change in depression score over time.

**P02.0470. The Health Benefits of Bike Sharing Systems can Outweigh the Risks in China, an Old "Kingdom of Bicycles"**

Wenjun Ma

*Wenjun Ma<sup>1</sup>, Tao Liu<sup>1</sup>, Jianxiong Hu<sup>1</sup>*

*1. Guangdong Provincial Center for Disease Control and Prevention, Guangzhou, China.*

**Abstract:** Objectives: This study aimed to quantitatively assess the total health benefits and risks of dockless bike sharing system on mortality rates respectively across China, and finally compare between them. Methods: The information of cycling and registered users between October 2016 to October 2017 in each province/municipality in mainland China was collected using online questionnaire survey and Software Development Kit (SDK) embedded into each bicycle application software. The benefits and risks of modal shift through dockless bike sharing system were respectively assessed for the direct and indirect exposure to air pollution, physical activities, and traffic accidents. Then the overall effects of bike sharing system were estimated by combing all the benefits and risks together. Results: The dockless bike sharing program was rapidly developed between October 2016 and October 2017 across China, with registered users increased from 4.8 million to 156.9 million and total distance of trips increased from 24.7 million km to 1,215.2 million km. As a result of physical activities, 35,842 deaths were avoided across China. 425 deaths were saved due to decreased ambient air pollution exposure which was caused by the decrease in traffic emission. However, 28 more deaths were caused by the direct air pollution exposure due to the increased inhalation during cycling, and 2234 more deaths were resulted in due to the traffic accidents. The combined results showed that a total of 34005 deaths have been saved, with most benefits in Guangdong province, and least benefits in Hainan province. Conclusions: The dockless bike sharing program has been rapidly developed across China, which have led to enormous mortality benefits to health.

## **P02.0480. Urbanization and Prevalence of Hypertension Based on 2017 American Heart Association Guideline for High Blood Pressure in the PURSE-HIS Cohort**

Mohan Thanikachalam

*Mohan Thanikachalam<sup>1</sup>, Ketch Cowan<sup>1</sup>, Kevin J. Lane<sup>2</sup>, Sadagopan Thanikachalam<sup>3</sup>*

- 1. Public Health, Tufts University School of Medicine, Boston, MA, United States.*
- 2. Environmental Health, Boston University School of Public Health, Boston, MA, United States.*
- 3. Cardiac Care Centre, Sri Ramachandra Medical Centre & RI, Chennai, Tamil Nadu, India.*

**Abstract:** **BACKGROUND:** In India, rapid urbanization has had a significant impact on the environment. Little is known about the impact of urban environment on the prevalence of hypertension (HTN). Here we assess the association between HTN and urbanization while controlling for cardiovascular risk factors in the PURSE-HIS cohort, India. **METHODS:** Based on census data, a random sample included 8080 participants (20-76 yrs of age; 56% female) from urban, semi-urban, or rural areas spread over 80 x 80 km. MODIS satellite land cover data at a 1 km x 1 km resolution was joined to participant's geolocated residential position in ArcGIS to assign urban and rural (crops, trees, shrubs and grass land cover) designations. HTN was diagnosed based on an average of 3 brachial blood pressure measures and the 2017 American Heart Association guideline for HTN diagnosis. Multivariable regression models tested the associations between urbanization measures and HTN, adjusting for age, sex, BMI, physical activity, smoking, socioeconomic, stress, anxiety, cholesterol and sodium intake levels and diabetes status. **RESULTS:** Based on census, prevalence in urban, semi-urban and rural communities was 49.3%, 41.3% and 31.6%, respectively. Based on MODIS urban, trees, grass and crops land cover, the prevalence was 46.7%, 39.7%, 37.9% and 35%, respectively. In fully adjusted models, urban participants (OR: 2.11 [1.89, 2.36]) and those residing in urban land cover (OR: 1.53 [1.37, 1.69]) had significantly higher odds for HTN when compared to participants in rural areas and crops land cover, respectively. **CONCLUSIONS:** With close to 50% of the urban population with HTN, there is a significantly higher prevalence of HTN based on the latest (2017) guidelines than previously reported. There is an independent association between urbanization measures and HTN after controlling for cardiovascular risk factors, suggesting unaccounted factors in the urban environment driving the prevalence HTN in urban India.

## **P02.0490. Sociodemographic Patterns of Exposure to Civil Aircraft Noise**

Matthew Simon

Chan School of Public Health, Boston, MA, United States.*

**Abstract:** Aim: Environmental exposures are often sociodemographically patterned, with greater exposures in communities with lower socioeconomic status (SES) and high racial/ethnic minority populations. Studies have shown an association between civil aviation noise and property values, but little is known about the racial/ethnic and SES exposure patterns. Our aim was to analyze the populations exposed to different noise levels around airports in the New England region of the U.S. to determine if noise exposure disparities were present. Methods: Noise contours, characterized as day-night average sound level (DNL), were developed for major New England airports (n=4) in 2010. U.S. Census blocks and noise contours >45 dB DNL with 1 dB increments were overlaid in a geographic information system; noise exposures were assigned to each census block based on the block centroid. We used t-tests to compare DNL levels between racial/ethnic minority ( $\geq 25\%$  minority population) and non-minority ( $< 25\%$  minority population) blocks, and between blocks with low ( $< 65\%$  of state median) and high ( $> 165\%$  of state median) household incomes. We also compared block noise levels with minority percentage and income using Spearman rank correlation coefficients (rs). Results: DNL for minority and non-minority blocks were the same (mean=49 dB, p-value=0.29), while the difference between low and high income was statistically significant (49 vs. 47 dB, respectively; p-value<0.01). Block average noise levels were not correlated with minority percentage (rs=0.01); lower median income was slightly correlated with increased noise (rs=0.10). Conclusions: Analyses to date suggest that income is more strongly associated with ambient aircraft noise concentrations within the New England region than with race/ethnicity. We will be investigating if these trends are reflected in other regions of the U.S. and determining if there are other population factors that would contribute to noise-related health disparities.

## **P02.0500. Noise Pollution and Preventive Measures**

Jeni Saykova

*Jeni N. Saykova<sup>1</sup>*

*1. Public Health, Medical University Sofia, Sofia, State, Bulgaria.*

Abstract: Noise pollution has an immense impact on the health condition of humans, as it represents a major factor influencing the environment. Moreover, it can badly influence humans' health by affecting the hearing analyzer, the nervous, the digestive, as well as the cardiovascular system. Nowadays, the majority of the population is mainly affected by the transport and aviation noise. The main aim of this research is to evaluate the noise pollution in the City of Sofia, Republic of Bulgaria and to examine the preventive measures regarding it. In that purpose, data from the monitoring system of the Ministry of Health (The Sofia Regional Health Inspectorate) for three-year-period 2015-2017 was used, including 48 spots (locations), divided as follows: 27% residential areas, 2.1% central city areas, 41% areas with very intensive traffic, 25% railways, 2.1% warehouses and 2.1% medical centers and sanatoriums. According to the results, no equivalent noise levels of 78-82 dB(A) have been reported during the recent years. There was only one spot with equivalent level between 73-77 dB(A). In further 11 spots (representing 22.9%) the noise levels ranged between 63-67 dB(A). Further on, the equivalent noise leveled between 58-62 dB(A) in 6 spots (12.5%). At 22 spots (45.8%) the average equivalents were higher. However, for the past three years, a noise reduction of 1-3 dB(A) ranging from 63-67 dB(A) was reported. Through its program for management and reduction of noise pollution, the Municipality of Sofia implements basic measures for prevention and protection of the public health, which encompass: Architecture and urban planning, transport and transport communications, green system and ecology, traffic police, controll, NPO. Despite the measures implemented, the number of spots with average noise levels between 68-72 dB(A) is the highest. To tackle this issue, a more complex approach is needed.

**P02.0510. Association of Exposure to Traffic-Related Air Pollution and Noise with Ischemic Heart Disease in Elderly People Living in Tokyo Metropolitan Area, Japan**

Haruya Sakai

*Haruya Sakai<sup>1</sup>, Tazuko Morikawa<sup>1</sup>, Hiroshi Koike<sup>1</sup>, Yukika Toda<sup>1</sup>, Akiyoshi Ito<sup>1</sup>, Tsuyoshi Ito<sup>1</sup>, Hiroki Kishikawa<sup>2</sup>, Kenichi Azuma<sup>3</sup>, Satoshi Nakai<sup>4</sup>, Iwao Uchiyama<sup>5</sup>*

- 3. Kindai University Faculty of Medicine, Osaka-Sayama, Japan.*
- 4. Yokohama National University, Yokohama, Japan.*
- 5. Kyoto University, Kyoto, Japan.*

**Abstract:** Objectives: This cross-sectional study examined the association of exposure to both traffic-related air pollution (TRAP) and noise with ischemic heart disease (IHD) morbidity in elderly people living in the Tokyo metropolitan area. Methods: Six thousand elderly people ( $\geq 65$  years old in April 2014) living in roadside or residential areas of Katsushika ward, Tokyo were randomly recruited. IHD, defined as diagnosis of IHD or history of medication for IHD, was determined by a questionnaire. To assess individual levels of TRAP exposure, annual concentrations of elemental carbon (EC) in 2009 were estimated using a plume dispersion model. For participants living in roadside areas, individual levels of exposure to road traffic noise (Lden) were calculated using distance attenuation formulas. The 24-h noise level was measured at five points in residential areas. A multiple logistic model was used to estimate associations of EC or noise exposure with IHD morbidity, adjusting for potential confounders as well as mutual adjustment for EC and noise exposure. Results: A total of 2,874 participants completed the questionnaire. The estimated mean annual exposure level of EC was  $0.73 \mu\text{g}/\text{m}^3$  (range:  $0.217\text{-}3.29 \mu\text{g}/\text{m}^3$ ). The estimated mean exposure level of noise for participants living in roadside areas was 59.5 dB (range:  $36.2\text{-}82.4$  dB). Noise levels in residential areas were  $< 65$  dB. The adjusted odds ratio (OR) for a  $1 \mu\text{g}/\text{m}^3$  increase in EC was 1.14 (95% confidence interval [CI]:  $0.83\text{-}1.52$ ), and 1.09 (95% CI:  $0.77\text{-}1.49$ ) after additional adjustment for noise. The adjusted OR for higher noise exposure ( $\geq 70$  dB) compared with lower noise exposure ( $< 65$  dB) was 1.26 (95% CI:  $0.72\text{-}2.08$ ), and 1.10. (95% CI:  $0.60\text{-}1.92$ ) after additional adjustment for EC. Conclusions: There are independent effects of TRAP and noise on IHD morbidity among elderly people living in the Tokyo metropolitan area.

## **P02.0520. Physical Activity may Modify the Association between Air Pollution and Brain Structure in the UK Biobank**

Melissa Furlong

*Melissa Furlong<sup>1</sup>, Gene E. Alexander<sup>2</sup>, Yann Klimentidis<sup>2</sup>, David Raichlen<sup>2</sup>*

*1. Community, Environment, and Policy, University of Arizona, Tucson, AZ, United States.*

*2. University of Arizona, Tucson, AZ, United States.*

**Abstract:** Air pollution and physical activity have been associated with structural brain outcomes, in opposite directions. Physical activity may modify the relationship between air pollution and health by increasing the rate of particulate deposition in the lungs. Sex may further modify these associations, as men experience higher rates of minute ventilation during physical activity. No studies have reported on these interactions in relation to brain structures. We used the UK Biobank, a prospective, population-based cohort, to examine overall and interaction effects between land use regression-derived measures of air pollution in 2010 (NOX, NO<sub>2</sub>, PM<sub>2.5</sub>, PM<sub>2.5</sub> absorbance, PM<sub>2.5</sub>-10, PM<sub>10</sub>, accelerometer-measured physical activity from 2013-2015, and sex on MRI measures of brain volumes and white matter hyperintensities in 2014-2015 (n=2,756). We used linear regression and controlled for a variety of covariates. Exposures were scaled to inter-quartile ranges and outcomes were standardized to a mean of 0 and standard deviation of 1. Overall, PM<sub>2.5</sub> absorbance (a measure of black carbon) was associated with more log white matter hyperintensities ( $\beta$  for a 1 IQR increase = 0.04, 95% CI 0.00, 0.09) and vigorous physical activity was associated with less white matter hyperintensities and more grey matter, white matter, and hippocampal volumes. Among men with high levels of vigorous physical activity, but not among women or men with lower levels of physical activity, air pollution was associated with less gray matter volumes (NO<sub>2</sub>  $\beta$ = -0.12, 95% CI -0.22, -0.03; PM<sub>2.5</sub>  $\beta$ = -0.09, 95% CI -0.18, -0.01; PM<sub>2.5</sub> Absorbance  $\beta$ = -0.09, 95% CI -0.17, -0.01; PM<sub>10</sub>  $\beta$  -0.07, 95% CI -0.13, 0.00; 3-way p interactions for reported models <0.05). Although vigorous physical activity is strongly and positively associated with improvements in overall brain structure, such activity may paradoxically exacerbate the inverse association between air pollution and brain structures among men.

**P02.0530. The Primavera Forest and Reduction of Premature Mortality Owing to Cardiovascular Disease in the Metropolitan Area of Guadalajara**

Arturo Curiel

*Arturo Curiel<sup>1</sup>, Citlali Curiel<sup>1</sup>, María G. Garibay<sup>1</sup>*

*1. Universidad de Guadalajara, Zapopan, Jalisco, Mexico.*

**Abstract:** Background/Aim Located to the extreme west of the Metropolitan Area of Guadalajara (AMG), the Primavera Forest biosphere reserve is traditionally recognized as an important ecosystem for the city, as winds pass through this forest before entering the city. The purpose of this study is to analyze the effect of the Forest on the health of the city's inhabitants, analyzing rates of premature mortality owing to cardiovascular disease. Method: AMG neighborhoods located less than or more than 10 km from the Primavera Forest were identified. An analysis of variance was conducted for the rates of premature mortality owing to cardiovascular disease in the specified neighborhoods. Mortality data was obtained from the Jalisco Department of Health. Findings: At the geographic level, the neighborhoods with the highest premature death rates (more than 40 premature deaths per 10,000 inhabitants/year) were identified and compared to those neighborhoods with the lowest rate of premature mortality (less than 15 premature deaths/10,000 inhabitants/year), resulting in an evident distribution of premature mortality with a positive correlation (the greater the distance from the Primavera Forest, the greater the premature mortality rate). The analysis of variance confirmed significant statistical differences (0.05) of premature mortality from cardiovascular disease rates in neighborhoods less than 10 kilometers from the Forest. Conclusions: The World Health Organization considers that the great majority of deaths related to the environment are due to cardiovascular disease (WHO, 2016). It has been demonstrated that Guadalajara's environmental determinants related to air polluting agents, and temperatures above 36°C affect the cardiovascular system; and that nearby forests provide air quality regulation services. The types of cardiovascular diseases with the greatest rates of premature death are ischemic heart disease (I20-I25) in first place and circulatory brain disease (I60-I69) in second.

## **P02.0550. Urban Greenness and Mental Health Disorders**

Timo Lanki

*Timo Lanki<sup>1</sup>, Anu W. Turunen<sup>1</sup>, Ann Ojala<sup>2</sup>, Pekka Tiittanen<sup>1</sup>, Tarja Yli-Tuomi<sup>1</sup>, Liisa Tyrväinen<sup>2</sup>*

*1. Health Security, National Institute for Health and Welfare, Kuopio, Finland.*

*2. Natural Resources Institute Finland (LUKE), Helsinki, Finland.*

**Abstract:** Background Natural elements in urban residential environments have been suggested to affect many aspects of human health. Mental health disorders are major contributors to the global burden of disability. There is currently inadequate evidence for the association between urban greenness and mental health. Methods A random survey was conducted in the greater Helsinki area in 2015/16 to collect information on adult ( $\geq 25$  years) population health, risk factors, and use of green space. Presence of a mental health disorder, depression or anxiety, was based on self-reported medication use. Percent coverage of green spaces, such as parks, forests and fields, within 1 km of residence was estimated using land-use data. Associations between residential greenness and mental health disorders were assessed using binary logistic regression. Models were adjusted for socioeconomic and life-style factors, use of summer cottage, residential blue space, and modelled traffic noise levels. Models will also be adjusted for NO<sub>2</sub>. Results There were 5835 participants with data on all covariates. Residential greenness was not associated with mental health disorders in the main analyses. Other indicators of exposure to green space, i.e. use of green space for recreation and use of summer cottage, were associated with health: e.g. OR for depression was 0.577 (95% CI 0.435-0.765) when comparing those visiting green space 1-2 times a week to non-visitors. However, the association between recreational activities and amount of green space was weak. Among persons with no frequent access to summer cottage, OR for the association between residential greenness and depression was 0.915 (95 % CI: 0.827-1.014) for a 10 % increase in green space coverage. Blue space was not associated with the outcomes. Conclusion We found limited evidence for the association between urban greenness and mental health disorders. In contrast, use of summer cottage was associated with lower prevalence of depression and anxiety.

## **P02.0570. Analysis of Physical Attributes and Occupant Reported Symptoms for 10,000 U.S. Homes**

Carl Grimes

*Carl Grimes<sup>1</sup>*

*1. Hayward Healthy Home Institute, Denver, CO, United States.*

**Abstract:** Background People are exposed to the indoor environment of homes for as much as 90% daily. Despite an increase in chronic disease with suspected environmental exposures, few epidemiological studies include the indoor environment of homes. The complexity of houses combined with the complications of individual susceptibility present a formidable obstacle to well-structured research. **Methods** An algorithm was developed to rank houses from 1 to 100 based on verifiable physical attributes and behaviours as reported by occupants in an Internet accessed survey. Questions also included a list of symptom complaints, plus whether occupants felt better when they left the house only to recur upon re-entry. Basic statistical analysis was conducted to identify combinations of attributes plus associations between those attributes and behaviours. **Results** Building on previous analysis from a smaller data set, cascading of the effects of attributes tended to result in lower scores than from singular attributes. Occupant responses to house attributes formed a skewed Bell curve, indicating houses are generally low scoring. Houses with cleanable surfaces, appropriate ventilation, moisture control, and current maintenance, for example, tended to have the fewest complaints. Houses that had difficult to clean surfaces, uncontrolled ventilation, dampness, and poor maintenance tended to have the greatest complaints. Anomalies included those who reported multiple complaints in high scoring houses and those who reported few complaints in low scoring houses. **Conclusion** General attributes of houses are common but individual houses are complex. Individuality of occupant experience is complex with frequent outliers. Patterns of apparent uniformity plus clusters of anomalies have been identified. The database of 10,000 houses continues to increase. Associations are beginning to be revealed, raising provocative and potential research questions, and contributions to, epidemiological investigations.

## **P02.0580. Epidemiological Study on Long-Term Health Effects of Wind Turbine Noise in Japan**

Tatsuya Ishitake

*Tatsuya Ishitake*<sup>1</sup>

*1. Environmental Medicine, Kurume University School of Medicine, Kurume, Japan.*

**Abstract:** We investigated whether long-term exposure to low-frequency noise generated by wind power facilities is a risk factor of sleep disorders. We performed an epidemiological study of living environment and health effects, surveying 9,000 residents ( $\geq 20$  years) living in areas with operational wind power facilities. In addition to basic attributes of the individuals, the survey items consisted of questions related to lifestyle, socioeconomic factors, health status, degree of annoyance towards noise, attitudes towards installation of wind power facilities, and responses to landscape. Sleep disorders were assessed using the Athens Insomnia Scale. To assess environmental noise in residential areas near the wind turbines, low-frequency sound exposure levels were measured at 50 community centers of the town. In some cases, the noise from the wind turbine was heard at locations that were 2,000 m away from the nearest wind power facility. Although below the auditory threshold, ultralow-frequency sound ( $< 20$  Hz) measured 46-72 dB (L<sub>Geq</sub>, WTN.). Moreover, several dominant components ranging from 50 to 250 Hz, exceeding the auditory threshold, were recorded; these appeared to be mechanical noise. The prevalence rate of sleep disorders was significantly higher for residents who reported subjectively hearing noise being (by approximately two-fold) than for those who did not. Moreover, the reported prevalence rate of sleep disorders was significantly higher (by approximately two-fold) in residents living at a distance of  $\leq 1,500$  m from the nearest wind turbine compared to that for residents living at a distance  $\geq 2,000$  m, suggesting an dose-response relationship.

## **P02.0590. A Combined Emission and Receptor-Based Approach to Modelling Environmental Noise in Toronto, Canada**

Tor Oiamo

*Tor H. Oiamo<sup>1</sup>, Daniel Rainham<sup>2</sup>, Claus Rinner<sup>1</sup>, Hugh W Davies<sup>3</sup>*

*1. Geography and Environmental Studies , Ryerson University , Toronto, ON, Canada.*

*2. Environmental Science , Dalhousie University , Halifax, ON, Canada.*

*3. School of Population and Public Health, The University of British Columbia, Vancouver , ON, Canada.*

**Abstract:** Aim: Environmental noise monitoring and modelling was completed to support a major revision of the Toronto Noise By-Law. The main objectives of this work were to describe and quantify outdoor ambient, urban noise levels and sources, and to identify areas and circumstances in Toronto with noise levels that could be injurious to health. Methods: Multi-criteria analysis and location-allocation modelling was utilized to identify monitoring sites with optimal coverage of differing spatial and population characteristics. Additional 'sites of interest' were identified in collaboration with various stakeholders. In total, 220 locations were monitored for a minimum duration of seven days in the summer in 2016. Observed noise levels were used to validate a road traffic noise emission and propagation model, and to identify a land use regression model that predicted the contribution of other sources to ambient noise levels throughout the city. Results: The equivalent 24-hour sound pressure level average for all sites was 62.9 dBA. This level varied significantly with different types of roads and land uses, and elevated noise levels were observed near sensitive areas such as schools, hospitals and long-term care facilities. The traffic noise emission model demonstrated a high level of covariance with observed noise levels, explaining 58%, 60% and 59% of variability during the daytime, nighttime and 24-hour periods, respectively. Combined with land use regression models to account for remaining noise sources, the hybrid models explained 64% to 71% of total noise variance for different time periods. Conclusions: The study showed that road traffic noise emissions account for most of the spatial variability of total environmental noise in Toronto. The combined approach to predict fine resolution noise exposures with emission and receptor-based models presents an effective alternative to other noise modelling approaches.

## **P02.0620. Urban Green Spaces and Cardiovascular Morbidity**

Mindaugas Malinauskas

*Mindaugas Malinauskas<sup>1</sup>, Ruta Minelgaite<sup>1</sup>, Vilija Malinauskiene<sup>2</sup>*

*1. Academy of Medicine, Lithuanian University of Health Sciences , Kaunas, Lithuania.*

*2. Population studies, Lithuanian University of Health Sciences , Kaunas, Lithuania.*

**Abstract:** Introduction. The objective of the present study was to explore associations between the distance and use of urban green spaces and the risk of cardiovascular morbidity. Methods. Randomly selected 5112 respondents (2195 men and 2917 women) participated in the study in Kaunas, Lithuania, that included self-reported sociodemographic, traditional cardiovascular risk factors, green space usage data and cardiovascular morbidity at follow-up (364 non-fatal cases of cardiovascular diseases (CVD)). SPSS 20.0 version software was used for statistical analysis. Distributions of the study cohort characteristics were tabulated by the distance from green spaces and by the use of city parks. We obtained estimates of the hazard ratio (HR) and 95% CI for non-fatal CVD using the multivariate Cox proportional hazards regression. Results. The proportion of park users among people in the 1st tertile of the distance to green spaces was significantly higher as compared to that among people from the 2nd and the 3rd tertiles (55.0%, 50.3% and 44.1%, respectively,  $p < 0.01$ ). The risk of non-fatal CVD among park non-users living farther away was statistically significantly increased (HR=1.66; 95% CI 1.01-2.73 after adjustment for a range of other risk factors) compared to park users living nearby in the whole population. A statistically significantly increased risk of non-fatal CVD was observed in women who were not park users and were from the 2nd and 3rd tertiles of the distance to green spaces, compared to the reference (HR=2.78, 95% CI 1.16-6.70), but this trend was not observed in men. Conclusions. An increase of the distance from the living place to green spaces among non park users statistically significantly increased the risk of non-fatal CVD compared to park users living a close distance to green spaces for the whole population and women who were not park users and living farther from green spaces.

## **P02.0630. Effect of Environmental Relationship between Fungal Exposure and Asthma in Children**

SungChul Seo

*Ki-yeon Kim<sup>1</sup>, Han-Jong Ko<sup>2</sup>, Kilyong Choi<sup>1</sup>, SungChul Seo<sup>1</sup>*

*1. Industrial health, Catholic University of Pusan, Busan, Korea (the Republic of).*

*2. Department of Environmental Engineering, Korea National Open University, SEOUL, SEOUL, Korea (the Republic of).*

**Abstract:** Background: Asthma is one of the most common chronic diseases and can be affected by environmental factors. It has been reported that exposure to indoor environmental factors can cause infantile asthma during infancy and childhood, but the previous studies are not yet clear. Climate change has recently been shown to increase indoor mold. Exposure to fungi is known to be directly related to the development of aggravation. Methods: This study was conducted from July 20, 2016 to September 30, 2016. The study was conducted on 90 household with children under the age of 7 who attend atopy school. The questionnaire surveyed allergic symptoms, social and demographic characteristics, and environmental characteristics. Environmentally hazardous substances were measured such as temperature, humidity, fine dust, volatile organic compounds, formaldehyde, bacteria, fungus, house dust mite, endotoxin. Results: According to the survey results, 9 patients (10%) were treated with asthma, 6 (6.7%) were asthmatic patients during the past 12 months, and 4 patients (4.4%) were asthmatic patients during the past 12 months. There were statistically significant differences in the direct effect of smokers in the family ( $P=0.0328$ ). High-filter vacuum cleaners collected 0.4222 CFU / m<sup>3</sup> in subjects without asthma, and 0.2222 CFU / m<sup>3</sup> in subjects with asthma. In addition, various results confirmed that asthma exacerbated by mold exposure. Conclusions: The results of this study suggest that exposure to fungal by infants and toddlers may play an important role in the development of asthma. In this study, we investigated the relationship between asthma and fungal concentration.

**P02.0640. Comparison of Heart Rate Variability Measurement Methods in Panels of Older Adults from the Outdoor Physical Activity and Health Study**

Robin Shutt

*Lisa Marie Kauri<sup>1</sup>, Robin Shutt<sup>1</sup>, Marie Mulholland<sup>2</sup>, Martin S Green<sup>2</sup>, Dave Stieb<sup>1</sup>*

*1. Healthy Environments and Consumer Safety Branch, Health Canada, Ottawa, ON, Canada.*

*2. Arrhythmia Monitoring Centre, University of Ottawa Heart Institute, Ottawa, ON, Canada.*

**Abstract:** Background: Between May 2013 and August 2015, participants in 5 separate Outdoor Physical Activity and Health study panels were asked to undergo endothelial function testing (EndoPAT, Itamar Medical) and ambulatory electrocardiogram (Holter) monitoring for heart rate variability (HRV) analysis. In research mode, the EndoPAT system also provides HRV data. Our objective was to compare HRV results from Holter and EndoPAT to determine if the two methods were comparable in a field study. Methods: 221 healthy, current non-smokers, aged 55-84 exercised outdoors daily for 30 minutes over the 10 week study period. Participants underwent weekly Holter monitoring (~5hrs; GE SEER), and EndoPAT testing before and after exercise. 5-minute windows of Holter data were analysed for HRV by trained technicians. Time matched EndoPAT HRV results were also collected. Pearson correlations between log-transformed Holter and Endopat HRV data were calculated, accounting for repeated measurements among participants, for all panels and participants, and by age, panel, body mass index (BMI) and sex. Results: Over the 5 panels, HRV was measured 3748 times using Holter monitors and 3680 times using EndoPATs. Participant characteristics varied between panels: mean age, 63-65 years, percent female, 56-71, and percent normal BMI, 14-46. For the 5 panels combined Holter and Endopat HRV time domain measures were strongly and significantly correlated (0.75 to 0.83,  $p < 0.0001$ ), while Holter and Endopat HRV frequency domain measures were less strongly correlated (0.28 to 0.63,  $p < 0.0001$ ). Correlations were consistent between panels, sexes, and BMI groups. Conclusion: Time domain HRV measures from Holter monitor and EndoPAT were strongly correlated. Where both endothelial function and HRV time domain are outcomes of interest, a single instrument to measure both parameters could reduce cost, analysis time, and participant burden.

## **P02.0650. Assessment of Indoor Microbial Exposures**

Meghan Davis

*Meghan F. Abstract: Indoor microbial exposures, including to colonizing opportunistic skin pathogens such as *Staphylococcus aureus*, can be common in household and school environments and may be linked to both infectious and chronic disease outcomes. We have adapted methods for culture-based and/or culture-independent assessment of *S. aureus*, *Escherichia coli*, and other microbes from indoor surface and dust samples and have applied these methods in a variety of settings, including household and school environments. Children may spend a disproportionately high percentage of their time in household and school environments and are a particularly important population to target since these exposures occur during critical developmental windows. Methods range from electrostatic-cloth-based assessment of microbial contamination of surfaces to quantitative polymerase chain reaction (qPCR) assessment of microbial genes in vacuum dust. The goal of this presentation is to describe these methods, discuss their strengths and limitations, and provide examples of how the methods can be applied to outcomes of methicillin-resistant *S. aureus* (MRSA) skin or soft-tissue infection, environmental enteropathy, and asthma. We will show that exposures to *S. aureus* and MRSA are common in household and school environments. We will link exposure to MRSA on household surfaces with MRSA re-colonization among urban and rural U.S. adults and children who previously cleared MRSA colonization. We will examine *E. coli* exposures in household environments as these relate to outcomes of environmental enteropathy among rural Peruvian children. We will demonstrate a high burden of exposure to *S. aureus* and genes related to staphylococcal enterotoxins in the homes of inner-city children with asthma, and link environmental exposure to asthma outcomes. We will discuss the implications for this work and how the methods may be adapted to assessment of other microbial exposures, including bacterial and fungal communities.

**Abstract:** The Japan Environment and Children's Study (JECS) measured serum concentrations of immunoglobulin E (IgE) antibodies against *Cryptomeria japonica* pollen during early pregnancy. *Cryptomeria*-specific IgE concentrations of class 2 or higher in pregnant women were most common (66%) at the Koshin Unit Center, located in a rural part of Central Japan. We investigated the relationship between pollen allergy (allergic rhinitis) and serum concentrations of *Cryptomeria*-specific IgE. Data were obtained from the JECS, in which serum concentrations of *Cryptomeria*-specific IgE in 4,178 subjects residing in Yamanashi Prefecture was measured at the Koshin Unit Center during February 14, 2011, and May 29, 2014. Simultaneously, self-reported information about presence or absence of pollen allergy symptoms was collected via a questionnaire. In the group reporting presence of pollen allergy symptoms, the mean and median serum *Cryptomeria*-specific IgE concentration class (on a scale of 0 to 6) was 3.14 and 3, respectively ( $n = 1852$ ), and the mean and median IgE concentrations were 22.4 and 12.6 UA/mL, respectively ( $n = 1827$ ). In the group reporting the absence of pollen allergy symptoms, the mean and median serum IgE concentration classes were 1.67 and 2, respectively ( $n = 2326$ ), and the mean and median IgE concentrations were 9.48 and 0.84 UA/mL ( $n = 2300$ ). Both the IgE concentration classes and actual IgE concentrations showed significant differences between the groups with and without pollen allergy symptoms ( $P < 0.001$ ). The area under the curve (AUC) for the receiver-operating-characteristic (ROC) curve prepared with IgE concentration as a continuous variable was 0.746, and the AUC was approximately the same, 0.741, even with IgE concentration classified on a scale of 0 to 6. When the optimal cut-off point was taken to be 3 (between 2 and 3), the sensitivity and specificity was 77.1% and 63.9%, respectively.

## **P02.0670. Partitioning the Indoor Microbiome: The Way Forward?**

Hal Levin

*Hal Levin<sup>1</sup>*

*1. Building Ecology Research Group, Santa Cruz, CA, United States.*

Abstract: Microbial communities found indoors (microbiome) are receiving increased attention, in large part due to high throughput DNA sequencing whose costs have dropped several orders of magnitude in the past decade. Funding supporting indoor microbial ecology surveys has incentivised cataloguing of various indoor microbiomes, particularly those with relatively high public visibility. While extreme weather events resulting in large-scale building damage motivated the public health community to identify indoor conditions associated with negative health effects, most recent research has not been purposed to find exposure relationships to health outcomes. Information on health effects of indoor microbiome exposure is limited from scientific perspectives, except for evidence supporting relationships to a relatively few (indoor) microbial agents and high incident infectious disease: e.g., *Legionella pneumophila*, the cause of Legionnaire's Disease and Pontiac Fever; *Mycobacterium tuberculosis*, the cause of tuberculosis; and, rhinovirus, the cause of the common cold. Norovirus, paramyxovirus, and orthomyxoviruses with epidemics or pandemics of measles, and influenza, including Asian and swine flu as well as the widespread, annual outbreaks of "seasonal flu." Potable water supply remains a significant microbial source, transport and exposure route with serious health consequences. Improving understanding of indoor microbial exposure assessments requires unified approaches for indoor sampling, as well as quantitative interpretation of built environment survey results. Extending the broader impacts of indoor microbial NGS surveys, results will require parallel improvements in monitoring building environmental factors and occupants, as well as well-structured interventions. Better "standardization" of sampling, analyses and QA/QC of NGS applications, and of building and occupant meta-data, can improve interpretive power of the growing collective of indoor microbiome surveys,

## **P02.0680. How Public Transport Strikes Affect the Health of Our Citizens?**

Margarita Triguero-Mas

*Margarita Triguero-Mas<sup>1</sup>, Erica Martinez<sup>1</sup>, Jose Barrera-Gómez<sup>1</sup>, David Agis<sup>1</sup>, Noemí Pérez<sup>2</sup>, Cristina Reche<sup>2</sup>, Andrés Alastuey<sup>2</sup>, Xavier Querol<sup>2</sup>, Catherine Pérez<sup>3</sup>, Xavier Basagaña<sup>1</sup>*

- 1. ISGlobal, Barcelona, Spain.*
- 2. IDÆA-CSIC, Barcelona, Spain.*
- 3. ASPB, Barcelona, Spain.*

**Abstract:** Public transport is seen as a key element to reduce air pollution levels in cities. We want to assess whether public transport strikes are associated with health outcomes (hospitalizations and mortality), and if they are mediated by the increase in air pollution. We compiled Barcelona-city data from government records for the period 2005-June 2016. We fitted quasi-Poisson time series regression models for each health outcome with strike occurrence as the explanatory variable. Models were adjusted for day of the week and holiday period. To account for temporal trends, we included a natural spline of time with 5 degrees of freedom per year. Mediation of the effect of strikes on health outcomes by air pollution was evaluated using the Baron and Kenny approach. During the study period, there were 208 days affected by a strike of the metro, train or bus systems. There was a median of 45 deaths per day, with a third of them being from cardiovascular or respiratory causes. In median, there were 74 cardiovascular or respiratory hospitalizations. During strike days there was between a 2.69% and a 45.96% increase in air pollution concentrations. We only detected increases of respiratory mortality during public transport strikes, which increased by 9% (95% CI: 1%, 18%). Stronger associations were found for metro strikes (reaching 66%). In those days, overall mortality and respiratory hospitalizations were also increased by around 16%. Associations between air pollutants and strikes occurrence were found mainly for nitrogen dioxide and black carbon, and especially during metro strikes. However, associations between strikes and health were unaffected by adjusting for air pollution levels, indicating no mediation. Our findings suggest that the increase in air pollution does not explain the increases in health outcomes. One possible explanation could be that days with strikes of the public transport system may magnify respiratory airways susceptibility due to the increase of stress.

## P02. Exposure Measurement, Modeling and Other Methodological Issues 2

### **P02.0690. Collecting and Repurposing Survey Data to Support Exposure Assessments**

Heidi Hubbard

*Heidi Hubbard<sup>1</sup>, Matt Jans<sup>1</sup>, Jessica Levasseur<sup>1</sup>, Cara Henning<sup>1</sup>*

*1. ICF International, Durham, NC, United States.*

Abstract: Exposure science requires consideration of chemical sources and human behaviors causing contact with those sources. Human behavior has become an increasingly important component of exposure assessment for consumer products, such as household cleaners and personal care products, and consumer articles, such as furniture and building materials. Quantifying exposure from these sources requires understanding population distributions of which products people use, how frequently they use them, and how much they use. Understanding these drivers of exposure is complicated because accurately measuring human behavior is complex and the average person uses a large number of consumer products. However, The Frank R. Lautenberg Chemical Safety for the 21st Century Act (reforming the Toxic Substances Control Act) requires prioritizing and regulating over 80,000 chemical substances based on their human health and ecological risk potential. Many of these chemicals are found in consumer products. Because overall risk is a function of exposure and hazard potential, we need new methods to estimate the population distribution of chemical exposure from consumer products. This presentation focuses on various survey methodologies, including both sampling and measurement techniques, for assessing the human behavior component of exposure. These include surveys focused on mail/internet questionnaires or phone/in-person interviews about behavior, with paired measurements of exposure media. Using real-world exposure surveys as case studies, we cover specific measurement methods and sampling methods. The measurement methods, such as event history calendars and time-use diaries, show particular promise for detailed consumer product exposure estimation; the sampling methods are used to select households and the specific people in households to capture exposure distributions across the population. We summarize these best practices for designing, conducting, and analyzing exposure surveys.

## **P02.0700. Data Infrastructure and Gateway for Environmental Health Research**

*2. Department of Geosciences, University of Arkansas, Fayetteville, AR, United States.*

*3. Department of Computer Sciences, University of Illinois at Chicago, Chicago, IL, United States.*

Abstract: Datasets that provide information about environmental quality are increasingly large and complex, and include both spatial and temporal information. These data require specialized skills to clean, organize, integrate with other environmental quality data and health outcome data, and analyze. The objectives of this study are to: 1) evaluate interest of the environmental health research and practice communities in a data infrastructure that integrates diverse environmental quality data, and that is accessible and analyzable through a user-friendly interactive Web-based gateway; and 2) test a prototype data infrastructure and gateway with potential end-users. Herein we present initial ideas about the data content and design of the data infrastructure and the envisioned functionality of the gateway. Our goal is to stimulate conversation with potential end-users.

## **P02.0710. Waste Impact on Children's Health: The Exposome Paradigm**

Dimosthenis Sarigiannis

*Dimosthenis A. Sarigiannis<sup>1</sup>*

*1. Chemical Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece.*

Abstract: Assessment of the health impacts (e.g. cancer, neurodevelopmental disorders and congenital anomalies) related to hazardous waste is a major scientific challenge with multiple societal implications. Most studies on the links between hazardous waste and health do not provide established mechanistic links between environmental exposure and disease burden, prohibiting us from exploring cost-effective waste management options. The exposome concept comes to overhaul the nature vs. nurture paradigm embracing a world of dynamic interactions between environmental exposures, endogenous exposures and genetic expression in humans, with a special focus on early developmental stages that have been proven determining for later life health status. In this context, the exposome paradigm provides a novel tool for holistic hazardous waste management taking into account their adverse effects on children's health. The complexity of assessing the health impact of hazardous waste is compounded by the variety of waste types, roughly categorized as (a) municipal, (b) agricultural, (c) e-waste, (d) hospital and (e) industrial. These various types of waste are associated with a broad range industrial chemicals and heavy metals. All these compounds form a complex mixture of highly variable composition in space and time-- accounting for differences in multimedia environmental transfer, persistence and bioaccumulation among the mixture components--to which children are exposed through multiple pathways and routes. Waste streams and the related contamination of environmental media are not viewed in isolation, but rather as components of the exotype, the vector of exposures an individual is exposed to over time. Waste management practices are thus assessed with regard to their effects on children's health at the individual and community level, taking into account intra-subject variability. The effectiveness of the exposome approach is demonstrated in the case of recycling.

## **P02.0720. Seasonal Variations of Exposure to Agricultural Pesticides in Residents Proximate to Vineyards: Sigxposome Study**

**Abstract:** Environmental exposure to pesticides is a major public health concern. Residential proximity to treated farmland has been associated with increased pesticides concentrations in residential dust and urine samples. The project investigates seasonal variations of exposure to agricultural pesticides of residents close to vineyards and of pesticide applicators (Beaujolais area, Auvergne-Rhône-Alpes Region), in a longitudinal study with repeated sampling of house dust, urine, blood and hair. We report pilot data for 19 residents (non-smoking men, aged 18-65). **Methods:** We sampled morning urine and house dust in July and October 2015. House dust: Efficiency and repeatability analyses of analytical methods (GC-MS, LC-MS/MS) allowed to retain 53 out of 62 preselected pesticides for analyses (recovery rate 70 -120%; RSD < 20%; LOQ 20-1000 ng/g dust). Urine samples: To screen presence of pesticides and their metabolites, a database containing 59 pesticides and 519 associated metabolites with their exact monoisotopic mass was set up. After solid phase extraction, the concentrated extracts of urine samples were analyzed in full scan mode by LC-HRMS. **Results:** 40 pesticides were quantified in dust, including 11 compounds of high public health priority. Among compounds with a prevalence >70% for one of the 2 sampling periods, significant seasonal variations in pesticide prevalence (n=10) and concentrations (n=14) was found with average concentrations higher in July than in October. 2 of the 3 pesticides metabolites detected in urine, specific to chlorpyrifos & chlorpyrifos-methyl and tebuconazole (both present in house dust), were confirmed by comparison with authentic standards. **Conclusion:** Our study showed seasonal variations of agricultural pesticides in housedust of residents close to vineyards. Correlation between residential dust and urine contamination and proximity to treated vineyards will be further explored. **Funding:** Auvergne-Rhône-Alpes Region; Métropole de Lyon.

## **P02.0730. Pesticide Residues in Soil, Water, Indoor Home Surface and Children's Hands**

Noppanun Nankongnab

*Noppanun Nankongnab<sup>1</sup>, Pakasinee Klaimala<sup>2</sup>, Pornpimol Kongtip<sup>1</sup>, Susan Woskie<sup>3</sup>*

Abstract: Pesticides are commonly used in Thailand for pest management both on the farm and in the home. This research measured pesticide residues in home and farm soil, drinking water, surface water sources on the farm, indoor home surfaces and the hands of farm children during the rainy and dry seasons in three provinces of Thailand (Nakhornsawan and Phitsanulok provinces where the farms used chemical pesticides and fertilizers and Yasothorn province where the farms were organic). The samples were analyzed for parent pesticides (20 organophosphates, 7 carbamates, 7 pyrethroids, glyphosate, paraquat and 3 triazines including atrazine) using standard AOAC analytical protocols. The results showed that for the organic farms in Yasothorn province, no pesticides were detected in soil, water, indoor surfaces or children's hand wipes during the dry season but fipronil-sulfone were found on children's hands, indoor home surfaces and cypermethrin were found on children's hands during the rainy season. In addition, some organophosphate pesticides were also found in pond water, home soil, farm soil and drinking water due to flooding in some areas of the province. In the chemical use farms of Nakornsawan and Phitsanulok province, the quantity of pesticides found in dry and rainy seasons were not significantly different. However, more types of pesticides were found in the rainy season. Pesticides that were found included paraquat dichloride and chlorpyrifos ethyl in soil farm, paraquat dichloride, chlorpyrifos ethyl and cypermethrin in home soil, atrazine, diazinon, carbofuran and ametryn in pond water, atrazine and profenofos in drinking water. Cypermethrin was also found in indoor home surface and children's hand wipes during both the rainy and dry seasons.

## **P02.0740. Exposure Characterization of a Cyanobacteria Harmful Algal Bloom (CHAB) at Clear Lake, CA: Data Collection Methodology**

Susan Viet

*Susan M. Viet<sup>1</sup>, Amanda Foss<sup>2</sup>, Karen Tait<sup>3</sup>, Edward Hudgens<sup>4</sup>, Peter S. Thorne<sup>6</sup>, Elizabeth Sams<sup>4</sup>, Mark Aubel<sup>2</sup>, Daniel Nelson<sup>4</sup>, Rebecca Ritter<sup>5</sup>, Elizabeth Hilborn<sup>4</sup>*

**Abstract:** Potentially harmful freshwater algal blooms of cyanobacteria (CHAB) are increasingly reported among US surface waters. Clear Lake in Lake County, CA is regularly impacted by CHABs during the spring through fall. As part of the US Environmental Protection Agency (EPA)'s effort to characterize CHAB exposures, air and water samples were collected at a pier adjacent to the shore at a public beach on five consecutive weekends during September-October, 2017. Air samples were collected for eight hours at 4-5 LPM; 20 Button samplers with fiberglass filters were collected in duplicate for endotoxin analysis; 20 closed-face, 25-mm MCE filters were collected in replicate for cyanotoxin analysis. Water samples were collected three times during each sampling day. A bucket was dropped from the pier to collect surface water from the top 10 inches; individual samples for analysis were collected from the bucket sample. Water samples were submitted to laboratories for analysis of endotoxin, phytoplankton, cyanotoxins, phycocyanin and chlorophyll-a. Water characteristics (temperature, pH, turbidity, dissolved oxygen) and weather condition (temperature, humidity, wind direction, wind velocity, rainfall) were recorded immediately following each sample collection period. Observations of human activities were made every hour throughout the sampling period, characterized by type of contact with water (no contact, hands/feet in water, partial submersion, full submersion, in boat, or on watercraft. The number of people engaging in each activity were counted by age group category (infants, toddlers, pre-adolescents, adolescents, adults). Dogs were counted due to recent reports of respiratory illness and death among dogs swimming in a CHAB. Initial results indicate that the sampling protocols allow for quantitation of cyanotoxins and endotoxin, and associated human activity. This abstract does not necessarily reflect EPA policy.

## **P02.0750. Chlorine Tolerance and Inactivation of Citrobacter Species Recovered from Wastewater Treatment Plants**

Mojisola Owoseni

*Mojisola C. Owoseni<sup>1</sup>, Anthony Okoh<sup>2</sup>*

*1. MICROBIOLOGY, FEDERAL UNIVERSITY LAFIA, NIGERIA, Lafia, Nigeria.*

*2. BIOCHEMISTRY AND MICROBIOLOGY, UNIVERSITY OF FORT HARE, ALICE, EASTERN CAPE, South Africa.*

**Abstract:** The increasing tolerance of some microbial pathogens in wastewater effluents to chlorine at the recommended dosages has threatened water security and public health safety. This study investigated the chlorine tolerance of some Citrobacter species recovered from two wastewater treatment plants in the Eastern Cape Province, South Africa. Effluent samples were collected from the clarifier of two wastewater treatment plants in the Eastern Cape Province, South Africa over a period of three months and were processed for isolation of Citrobacter species using standard methods. Presumptive bacterial isolates were identified by 16S rRNA gene sequencing (n=20) and the Basic Local Alignment Search tools (BLAST) analysis. Bacterial isolates at initial population of 8.3 log were screened at the recommended free chlorine of 0.5 mg/L and the chlorine lethal dose and inactivation kinetics at lethal doses were examined. Data was analysed using analysis of variance (IBM SPSS Statistics 23) and linear regression (Origin Pro 2017). The BLAST results revealed a 99% similarity of bacterial isolates to Citrobacter genus. The test bacteria (n=20) at the recommended chlorine dose of 0.5 mg/L gradually declined from 4 - 5 log with chlorine residuals between 0.12 - 0.46 mg/L after 30 min. Treatment at higher chlorine doses (0.75 - 1.5 mg/L) revealed a significant reduction ( $p < 0.05$ ) in viability of bacterial population and complete inactivation of Citrobacter species at lethal doses of 0.75 and 1.0 mg/L in 30 min. Increase in bacterial inactivation significantly correlated ( $p < 0.5$ ) with increase in contact time and R2 values ranged between 0.73 - 0.92 for the three Citrobacter species. Treatment at 0.5 mg/L dosage showed a poor removal efficiency by chlorine while an increase in chlorine concentration at 0.75 - 1.0 mg/L resulted in higher inactivation of Citrobacter sp. and is hereby proposed as an alternative dose to check bacterial tolerance.

## **P02.0760. Urban Mind: Using Smartphone Technologies to Investigate the Impact of Nature on Mental Wellbeing in Real Time**

Ioannis Bakolis

*Ioannis Bakolis<sup>1</sup>, Ryan Hammoud<sup>2</sup>, Michael Smythe<sup>3</sup>, Johanna Gibbons<sup>4</sup>, Neil Davinson<sup>4</sup>, Stefania Tognin<sup>2</sup>, Andrea Mechelli<sup>2</sup>*

- 2. Psychosis Studies, King's College London, London, United Kingdom.*
- 3. Nomad Projects, London, United Kingdom.*
- 4. J and L Gibbons, London, United Kingdom.*

**Abstract:** It has been suggested that exposure to natural features within the urban environment can have beneficial effects on mental health. However, most existing evidence comes from studies that used a cross-sectional design and did not consider the interaction with individual characteristics such as age, lifestyle and vulnerability to mental illness. We developed a smartphone-based tool (Urban Mind; [www.urbanmind.info](http://www.urbanmind.info)) to examine how exposure to natural features affects momentary mental wellbeing in real-time and real-world environments and how this depends on individual characteristics. The Urban Mind tool was used to monitor 108 anonymous volunteers who completed a total of 3013 assessments over a one-week period. Longitudinal associations between self-reported environmental characteristics and momentary mental wellbeing were investigated using random intercept linear models. Specific natural features such as being outdoors, seeing trees, hearing birdsong and seeing the sky, had beneficial effects on momentary mental wellbeing (all  $p$  values  $< 0.001$ ). These associations were still evident up to 7.5 hours after a single exposure had taken place, indicating time-lasting benefits. In addition, these associations were stronger in people with higher trait impulsivity - a psychological measure of one's tendency to behave with little forethought or consideration of the consequences, and a predictor of higher risk of developing mental health issues. Our investigation extends existing evidence on the benefit of nature on mental wellbeing, by demonstrating time-lasting effects that interact with an individual's vulnerability to mental health issues. These findings have potential implications both from the perspectives of global mental health and urban planning and design. We are currently trialing the Urban Mind app in clinical populations.

## **P02.0780. Polydimethylsiloxane Wristbands as Tools for Estimating Exposure to Semi-Volatile Organic Compounds**

Joseph Okeme

- 2. University of Toronto, Toronto, ON, Canada.*
- 3. Chinese University of Hong Kong, Sha Tin, Hong Kong.*

**Abstract:** Semi-volatile organic compounds (SVOCs) are ubiquitous in the environment owing to their use in many household products, consequently presenting opportunities for human exposure and a range of potential health effects. We aimed to improve exposure assessment by developing personal passive air samplers (PPAS) as inexpensive and easily used tools. PPAS are expected to better capture an individual's exposure circumstances compared to either stationary active or stationary passive air samplers and are much less burdensome than active personal samplers. Here, we tested commonly available silicone rubber or polydimethylsiloxane (PDMS) wristbands as PPAS for measuring levels of SVOCs in non-industrial indoor environments. Target SVOCs were 6 phthalates, 23 brominated flame retardants (BFRs) and 16 polycyclic aromatic hydrocarbons (PAHs). In total, 14 study participants in Toronto, Utrecht and Hong Kong, chosen as a sample of convenience, wore PDMS wristbands continuously for a week while leading their normal lives. Wristband samples were extracted and analysed for target SVOCs using gas chromatography mass spectrometry. Five phthalates and 7 PAHs had detection frequencies >70%. These compounds are found in both gas and particle phases. BFRs had levels generally < method detection limit (MDL), and PAHs and phthalates had levels ranging from These findings show that PDMS wristbands are convenient to use and promising for providing estimates of an individual's exposure to SVOCs.

**P02.0790. Commuting Exposures to Particulate Air Pollution in Three Canadian Bus Transit Systems: The Urban Transportation Exposure Study**

Keith Van Ryswyk

*Keith Van Ryswyk<sup>1</sup>, Ryan Kulka<sup>1</sup>, Greg Evans<sup>2</sup>, Sun Liu<sup>1</sup>, Kelly Sabaliauskas<sup>2</sup>, Angelos Anastasopoulos<sup>1</sup>, Lance A. Wallace<sup>3</sup>, Scott Weichenthal<sup>1</sup>*

- 1. Health Canada, Ottawa, ON, Canada.*
- 2. Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, ON, Canada.*
- 3. Consultant, Santa Rosa, CA, United States.*

**Abstract:** Background: Health Canada's Urban Transportation Exposure study was designed to assess levels of air pollution in Canadian transport environments. As Canadians spend approximately 52 minutes of their day commuting, this environment may contribute a larger proportion of their daily exposure to traffic-related air pollution (TRAP)". Identifying factors related to bus commuting TRAP exposure is key to its mitigation. Methods: From 2010-2013, sampling was conducted using personal monitors in bus transit environments of Toronto, Ottawa, and Vancouver. In each city, data were collected during 3-week sampling campaigns in the summer and winter for fine particulate matter (PM<sub>2.5</sub>), ultrafine particulates (UFPs), and black carbon (BC). Buses were classed as natural gas, electric, hybrid electric/diesel, clean diesel, post 2000 diesel, or pre 2000 diesel. Stations/stops were classed as bus stop, above grade bus station, or below grade / indoor bus station. Particulate air pollution levels were compared between cities, seasons and waiting vs riding. The impact of bus propulsion type and stop/station design on air pollution exposures were evaluated using linear mixed-effect models. Model development included screening for potential confounders such as meteorological factors and land use. Results: Levels of PM<sub>2.5</sub>, UFPs, and BC were similar between cities and with higher UFPs concentrations observed during winter. In Toronto, bus stations had higher (65%, 95%CI: 48-84%) PM<sub>2.5</sub> levels relative to bus stops. Similar differences were seen for BC. Compared to pre-20000 diesels, hybrid electric/diesel buses reduced exposures for PM<sub>2.5</sub>, UFPs, and BC in all three cities. Conclusions: The personal exposure data collected in this study provides a benchmark of Canadian commuter exposure for bus transit and provides evidence of the potential air quality benefits of ventilating indoor/below grade bus stations and replacing older bus models.

## **P02.0800. Air Pollutant Exposure Measured with Low-Cost Sensors: Results from a 50-Node Network in Pittsburgh**

Albert Presto

*Albert Presto<sup>1</sup>, R Subramanian<sup>1</sup>, Carl Malings<sup>1</sup>, Naomi Zimmerman<sup>2</sup>, Rebecca Tanzer<sup>1</sup>, Aliaksei Hauryliuk<sup>1</sup>, Srinu Kumar<sup>1</sup>*

*1. Carnegie Mellon University, Pittsburgh, PA, United States.*

*2. University of British Columbia, Vancouver, BC, Canada.*

**Abstract:** Background: Networks of low-cost air pollutant sensors offer promise for characterizing pollutant concentrations at high spatial and temporal resolution. While numerous studies have described calibration of these sensors and deployments of a few nodes, few studies have evaluated the performance of citywide or other large-scale sensor networks. Methods: We deployed a network of 50 Real-time, Affordable, Multi-Pollutant sensors (RAMPs) for one year in Pittsburgh, PA, USA. The RAMP uses electrochemical sensors to measure CO, O<sub>3</sub>, NO<sub>2</sub>, and either NO or SO<sub>2</sub>; a nephelometer to measure PM<sub>2.5</sub> mass concentrations; and NDIR to measure CO<sub>2</sub>. The RAMPs were deployed in a variety of urban environments representing variations in traffic, industrial, and restaurant source intensities. Results: There is significant spatial variation in all measured pollutants across the RAMP network. Spatial variations manifest across multiple temporal scales. Long-term (annual) differences between nodes are driven by a combination of proximity to sources and nearby land use, whereas industrial and other point sources drive episodic hotspots in daily or hourly concentrations. Comparison of the distributed network to EPA reference monitors enables determination of conditions when the reference monitor does not provide representative concentrations (e.g., daily PM<sub>2.5</sub> within 1 µg m<sup>-3</sup>) over the wider domain covered by the RAMPs. Both median and 95th percentile PM concentrations are higher across parts of the city during periods with southerly winds, compared to westerly winds when regional pollution dominates. The higher concentrations are not seen at the regulatory site, indicating the value of a high density low-cost network for exposure measurements. Conclusions: Distributed networks of low-cost monitors can provide rich spatial and temporal measurements of air pollutant concentrations at a citywide scale.

## **P02.0810. Development of a Novel DNPH Cartridge for Capturing Gaseous Acrolein**

Miyuki Noguchi

*Miyuki Noguchi<sup>1</sup>, Yoshihiro Suzuki<sup>2</sup>, Fumiko Tanaka<sup>2</sup>, Takanori Enomoto<sup>2</sup>, Akihiro Yamasaki<sup>1</sup>*

*1. Seikei University, Musashinoshi, Tokyo, Japan.*

*2. SIBATA Scientific Technology LTD., Soka, Japan.*

**Abstract:** A DNPH-loaded cartridge has been widely used for capturing gaseous aldehydes such as acrolein. The cartridge is packed with silica gel beads loaded with DNPH, and the aldehydes introduced to the cartridge will be bonded to DNPH to form derivatives. The derivatives are then extracted with a solvent to be analyzed with HPLC. However, acrolein has a double bond, and the derivative with DNPH is subject to be bonded with a DNPH molecule in the vicinity to form the other derivative, a dimer. The dimer is also subject to react with DNPH to form a trimer. The oligomerizations of the DNPH-acrolein derivatives would make the accurate measurement of acrolein in the air difficult, and it is necessary to prevent the oligomerization reactions for the accurate quantification of acrolein. In this study, we developed a new type of the cartridge for capturing and holding gaseous acrolein. The cartridge is packed with DNPH-loaded silica gel beads modified with TEMPO (2,2,6,6-tetra methylpiperidine 1-oxyl) or BHT (dibutyl hydroxytoluene) as oligomerization inhibitors. A known amount of liquid acrolein was injected to the cartridge, and the cartridge was held for a certain period under a controlled temperature condition. Then the acrolein in the cartridge was extracted with acetonitrile, and quantified with HPLC. By the addition of TEMPO, the formation of DNPH-acrolein dimer or trimer was remarkably reduced compared with the case without TEMPO. The prevention of the oligomerization reaction was found to depend on the initial pH of the cartridge: The lower pH is preferable to prevent the oligomerization. The addition of BHT also reduced the formation of oligomers. By using the DNPH cartridge with TEMPO (0.001wt%), about 70% of the acrolein injected to the cartridge was held unchanged for 7 days under 5°C.

## **P02.0820. An Evaluation of a Long-Term Air Sampling Technique Used to Assess Temporal and Spatial Variation to Volatile Organic Compounds from Vapor Intrusion**

Alan Rossner

*Alan Rossner<sup>1</sup>, Benjamin Stone<sup>1</sup>, Marley Carroll<sup>1</sup>, Michelle Crimi<sup>1</sup>, Justin Miceli Miceli<sup>1</sup>*

*1. Institute for a Sustainable Environment, Clarkson University, Potsdam, NY, United States.*

**Abstract:** Assessing vapor intrusion (VI) contamination is challenging because of the temporal and spatial variation that can occur within the building envelope. Day-to-day changes in concentration can vary by one or even two orders of magnitude, thus making it difficult to target sample time representative of occupant exposure in occupational and residential settings. The aim of this study was to evaluate the performance of a long-term flow controller (2 weeks) in buildings with VI problems for both seasonal and spatial variabilities. Long-term capillary flow controllers (CFC) connected to evacuated canisters were used to characterize VOCs from VI at four locations with a known history of VI occurrence. The low flow rate CFC provided flow rates ranging from 0.1 to 0.3 mL/min. Evacuated canisters and thermal desorption (TD) tubes were placed side-by-side in four locations inside two large buildings for 14 consecutive days. The sampling events occurred during four seasons in 2017. Six-liter canisters equipped with a diaphragm flow controller were used to collect 24-hour samples for 14 consecutive days, while a set of two canisters equipped with the CFC were used to collect 14-day samples. TD tubes were used to sample for 3, 7, and 14-day intervals. Analysis occurred at Clarkson University using a MARKES CIA Advantage/Unity 2 connected to a GC/MS. To date, four sampling events have been completed resulting in over 500 canister samples assessing the temporal and spatial variability. The results have shown the CFC are within a 95% CI in 15 of the 16 tests ( $p > 0.05$ ). Regression analysis between the CFC and diaphragm flow controllers generated a regression of 0.95. The new canister method captures the advantages of both diaphragm flow controllers and sorbent tubes, without their limitations, by allowing for long-term (>2 weeks) sample collection and characterization of average VOCs in buildings at risk for VI.

**P02.0840. Determination of Personal and Indoor/Outdoor Concentrations of Nicotine for Passive- or Non-Smoker**

Takashi Amagai

*Takashi Amagai<sup>1</sup>, Yoko Kai<sup>1</sup>, Yuichi Miyake<sup>1</sup>, Satoshi Nakai<sup>2</sup>*

Abstract: Although second-hand smoke is one of the public health problem, few reports quantitatively evaluated the exposure amount of environmental tobacco smoke (ETS) by passive- or non- smoker. This is due to the fact that few analytical methods has been developed that can measure low level and long-term exposure to ETS. Since we selected nicotine as a marker of ETS that contains thousands of chemicals in previous studies, we have developed an analytical method for indoor, outdoor and personal nicotine concentrations. The sampler consisted of collection filter and filter holder. The nicotine was collected on the quartz fiber filter impregnated with sodium hydrogensulfate. The collected filter was extracted by ultrasonication with distilled water, and nicotine was separated and analyzed by LC-MS/MS. The method have high sensitivity and selectivity. Detection limit of nicotine by LC-MS/MS was 2.5 pg, which correspond to 7 ng/m<sup>3</sup> for 24 hour collection using the developed sampler. It prevents re-volatilization and also ensures storage stability by collecting nicotine as a sulfate salt. We have also developed nicotine active sampler using the quartz fiber filter impregnated with sodium hydrogen sulfate. Detection limit of nicotine by the active sampler was 0.05 ng/m<sup>3</sup> for 24 hour collection at a flow rate of 0.1 L/min. The preliminary survey of indoor/outdoor concentrations of nicotine were performed. Nicotine concentrations indoors/outdoors in the six houses where passive- or non- smoker lived in were determined. Outdoor nicotine concentrations were ranged 1.0 to 19 ng/m<sup>3</sup>, and indoor nicotine concentrations were ranged 1.0 to 133 ng/m<sup>3</sup>. Nicotine concentrations of 2 rooms in 6 houses (33 - 133 ng/m<sup>3</sup>) were significantly higher than other rooms (1 - 19 ng/m<sup>3</sup>). This may be due to third-hand smoke in the rooms.

## **P02.0850. A Critical View of Low Cost Sensor System Networks for Air Quality**

Alena Bartonova

*Alena Bartonova<sup>1</sup>, Nuria Castell<sup>1</sup>, Franck Dauge<sup>1</sup>, Mirjam Fredriksen<sup>1</sup>, Sonja Grossberndt<sup>1</sup>, Britt Ann Hoeiskar<sup>1</sup>, Hai-Ying Liu<sup>1</sup>, Philipp Schneider<sup>1</sup>*

*1. NILU Norwegian Institute for Air Research, Kjeller, Norway.*

**Abstract:** Low-cost sensor systems (LCSS) represent a disruptive change in air monitoring, and pose numerous challenges. The Citi-Sense project (<http://co.citi-sense.eu>) that operated between 2012 and 2016 in nine European cities, provides a vivid illustration. Three use cases were deployed, on ambient air quality, on indoor environment at schools, and on the quality of urban spaces, with at times, over 300 LCSSs in use simultaneously. We aimed at providing air quality information to stakeholders, but without a clear prior idea of the purpose and DQOs: we felt that information generated by LCSSs can support several objectives. Our knowledge as to what are capabilities of the technology was low and expectations were high. Any large-scale use of LCSS requires to deploy two enabling technologies, sensing technology and information and communication technologies for data transmission, storage and use, and has a number of steps. We have deployed LCSS's from 9 different producers, in a variety of climatic conditions, from Oslo (Norway) to Haifa (Israel), and Edinburg (United Kingdom) to Beograd (Serbia). We thus demonstrate intercomparison issues as well as the dependency of monitoring results on local conditions. Despite extensive field calibration and co-location, we were not able to quantify uncertainty sufficiently to provide comparable data across locations. However, we successfully developed an accurate real-time map, unavailable using other current methods, addressing the interest in real time information. Using LCSSs as personal monitors has similar challenges as traditional methods, and some new ones. User feedback showed that at this stage (2015), only a special interest group can successfully use the devices. We believe there is a great potential to the LCSSs, but also serious obstacles. Quality assurance and quality control of data needs further development. Correct communication of the results and expectation management are a second main barrier to successful use of LCSS.

**P02.0860. Environmental Influences on Health Outcomes-Integrating Real-Time Exposure Measures from Homes into Longitudinal Cohort Studies: Lessons from the Field**

Katherine Sward

*Scott Collingwood<sup>1</sup>, Ramkiran Gouripeddi<sup>2</sup>, Bob Wong<sup>3</sup>, Katherine Sward<sup>3</sup>*

**Abstract:** In North America, adults and children of all ages spend much of their time indoors with the home where a majority of time is passed. Exposure to respirable particulate matter (PM) of varying sizes has been linked to cardiovascular and respiratory problems. Exposures to PM<sub>2.5</sub> contribute to childhood respiratory ailments such as asthma. Utah collaborators with pediatric cohorts aligned with the National Institutes of Health (NIH) ECHO program and NIH PRISMS program conducted pilot projects aimed at using innovative, real-time, low-cost air quality sensors to provide spatio-temporal records of particulate matter (PM) exposures. The projects evaluated participant acceptance, feasibility, and efficacy in building exposure profiles using instrumentation, extant data, models and health information integrated with a single informatics platform. The PM sensors are small and feature secure Wi-Fi and data storage capability. More than 30 participant homes had one outdoor and two indoor sensors capturing time stamped PM counts every minute which were aggregated to daily data for initial analyses. Participants were supportive of using their personal Wi-Fi for sensor data transmission. From the PRISMS project (n=6), mixed modeling showed the daily estimated marginal mean level of small (PM<sub>2.5</sub>) and large (PM<sub>10</sub>) particle counts was lower indoors than outdoors ( $p < 0.001$ ). Among 6 pediatric asthmatic participants reporting daily asthma treatment usage via eAsthma Tracker, indoor PM counts were not related to treatment usage ( $p > 0.05$ ). Higher levels of PM<sub>2.5</sub> outdoors were related to increases in asthma treatment ( $p < 0.001$ ) while outdoor PM<sub>10</sub> were not related to treatment usage ( $p = 0.52$ ) in this small sample. These pilot projects demonstrated the feasibility of gathering environmental exposure data from low-cost sensors at a very fine level of resolution, and ability to integrate and analyze data across disparate data sources using the Utah PRISMS developed infrastructure.

## **P02.0890. Spatial and Temporal Characterization of Chemical Emissions Aboard the AC130 Gunship**

Christin Grabinski

*Christin M. Grabinski<sup>1</sup>, Jerimiah Jackson<sup>1</sup>, Megan Steele<sup>1</sup>, Kelsey Lee Schafer<sup>2</sup>, Dirk Yamamoto<sup>1</sup>*

*1. USAF School of Aerospace Medicine, Air Force Research Laboratory, Dayton, OH, United States.*

*2. Airman Systems Directorate, 711th Human Performance Wing, Wright Patterson AFB, OH, United States.*

**Abstract:** Aerial gunships present a unique exposure environment where byproducts from weapons firing are released into the aircraft cabin, potentially exposing the aircrew to hazardous agents. Certain agents, such as carbon monoxide (CO), can have a cognitive effect, which is not only a health concern, but also a concern for operational success. We completed a comprehensive exposure assessment in the cabin and cockpit of two models of the gunship, the AC130J and AC130W. During the assessment, firing exercises were completed using the 105-mm Howitzer and 30-mm GAU/23A Bushmaster II gun both individually and simultaneously. Air sampling for CO, ultrafine particles and metals was conducted near the breathing zone of aerial gunners, weapons systems officers, and pilots and near the regulator intake for oxygen masks in the main cabin to characterize the distribution of contaminants throughout the aircraft. Video monitoring was used to correlate gunner activities with CO levels throughout the aircraft. CO levels in the breathing zone of gunners during firing activities exceeded a 100-ppm action level, but not a 200-ppm exposure limit. CO in the cockpit and near the weapons systems officers was 5-10 times lower than the action level at peak levels. Ultrafine particles reached the cockpit during firing at levels about four times lower than in the breathing zone of the 105-mm Howitzer gunner. Lead was found at detectable levels in the breathing zone of gunners, as well as in the cockpit, but levels did not exceed an action level of 0.025 mg/m<sup>3</sup>. Based on the findings from this study, CO exposure during firing aboard the gunship has the greatest potential to affect the gunners and is not likely a threat to pilots and weapons systems officers. Continuous CO monitoring in the breathing zone of aircrew members would be an effective approach to identify conditions associated with dangerous exposure levels during future missions.

**P02.0900. The Effects of Facemasks on Airway Inflammation and Endothelial Dysfunction in Healthy Young Adults: A Double-Blind, Randomized, Controlled Crossover Study**

Tianjia Guan

*Tianjia Guan<sup>1</sup>, Songhe Hu<sup>1</sup>, Yiqun Han<sup>1</sup>, Tong Zhu<sup>1</sup>*

*1. Peking University, Beijing, China.*

**Abstract:** Background Facemasks are increasingly worn during air pollution episodes in China, but their protective effects are poorly understood. We aimed to evaluate the filtration efficiencies of N95 facemasks and the cardiopulmonary benefits associated with wearing facemasks during episodes of pollution. Results We measured the filtration efficiencies of particles in ambient air of six types of reusable N95 facemasks. The most effective one was used in a double-blind, randomized, controlled crossover study, involving 15 healthy young adults, conducted during 2 days of severe pollution in Beijing, China. Subjects were asked to walk along a busy-traffic road for 2 hours wearing authentic or sham N95 facemasks. Clinical tests were performed four times to determine changes in the levels of biomarkers of airway inflammation, endothelial dysfunction, and oxidative stress within 24 hours after exposure. The facemasks removed 48-75% of ambient air particles between 5.6 and 560 nm in diameter. After exposure, the exhaled nitric oxide level and the levels of interleukin-1 $\alpha$ , interleukin-1 $\beta$ , interleukin-2, interleukin-6, and tumor necrosis factor- $\alpha$  in exhaled breath condensate increased significantly in all subjects; however, the increases in those wearing authentic facemasks were statistically significantly lower than in the sham group. No significant between-group difference was evident in the urinary creatinine-corrected malondialdehyde level, augmentation pressure, or the augmentation index. Compared to the sham group, the ejection duration of subjects wearing authentic facemasks was higher after exposure. Conclusions In young healthy adults, N95 facemasks partially reduced acute particle-associated airway inflammation, but neither systemic oxidative stress nor endothelial dysfunction improved significantly.

## **P02.0910. Developing Field Calibration Models for Non-Reference Monitoring Techniques: A Case Study of Light Scattering Laser Photometers**

John Pearce

*John L. Pearce<sup>1</sup>, Adwoa Commodore<sup>1</sup>*

*1. Public Health Sciences, Medical University of South Carolina, Charleston, SC, United States.*

**Abstract:** Non-reference monitoring (NRM) techniques need to be evaluated against reference measurements to ensure appropriate interpretation and application. The aim of this study was to develop a field calibration model for the DustTrak DRX, a NRM light scattering laser photometer that simultaneously measures multiple size fractions of particulate matter (PM), in order to adjust data results based on co-located measurements taken with federal reference (FRM) and equivalent (FEM) methods. We deployed five DRXs at the EPA NCORE site in Columbia, South Carolina, from January 16th through February 7th 2018 to collect co-located data with FRM/FEM PM10 and PM2.5. We evaluate results with descriptive statistics, correlation coefficients, ratios of the overall means (DRX/FEM), overall mean bias, and normalized mean bias. To adjust NRM data, we develop a field calibration model using the framework of a generalized additive model (GAM). During the co-location weather exhibited temperatures ranging from -4.4 to 21.7 °C, humidity ranging from 14 to 100% and wind speed ranging from 0 to 9.3 m/s. PM conditions, although FRM were not presently available, were perceived to be low-to-moderate as the overall average FEM PM2.5 was 6.8 (standard deviation = 5.1) µg/m<sup>3</sup> and the 5-95% range was 2.7 to 12.6 µg/m<sup>3</sup>. Correlations between DRX measurements and hourly FEM PM2.5 measures were strong ( $r = 0.90$  to  $0.91$  and overall mean ratios (DRX/FEM) revealed under reporting of the DRXs (values between 0.64 and 0.71). Mean biases ranged from 1.9 to 2.4 µg/m<sup>3</sup> and normalized mean biases were less than 25% (17.2 - 23.6%). Our GAM performed well as the variability in FEM measured PM2.5 was well explained ( $R^2 = 0.82$ ), the predictive error was relatively low (root-mean-square-error = 2.46), and mean biases of predictions were zero. Our approach allows us to detect and remove NRM instrumental biases and thus improves the comparability and interpretation of data collected using non-reference techniques.

## **P02.0931. Mapping Hotspots of Environmental Burdens in the Framework of Cumulative Risk Assessment in Wallonia**

*2. Chronic Risks, Scientific Institute of Public Service (ISSeP), Liège, Belgium.*

*3. Air Quality, Scientific Institute of Public Service (ISSeP), Liège, Belgium.*

**Abstract:** Differential exposure to multiple environmental burdens and benefits across populations with varying vulnerability can contribute heavily to health inequalities. Developing environment and health information systems has therefore become a major focus for public health. In this framework, the Scientific Institute of Public Service (ISSeP) works on building an integrated approach of environmental exposure assessment in the Walloon region, Belgium. This study develops an index-based approach to assess the multiple environmental burdens at regional level and detailed local resolution that can be used in a spatial web tool. Indicators are based on environmental measure of pollutants in ambient air and soil, and on stressors for citizens related to noise and radon. Two methods were combined to identify both zones where pollutions and stressors are cumulating, even below threshold values, and zones where the exceedance of threshold values is frequent. First, a ratio value is calculated for each spatial unit (i.e. statistical sector) by dividing the indicator value by the corresponding threshold values quoted by the WHO or Walloon legal limit values. Other pollution sources (roads, industries, landfills, mine heaps, ...) are estimated by specific GIS processing based on Euclidean distance analysis which vary in relation to pollution effect to population. Secondly, environmental indicators are mapped as proportions of spatial units where the level of potential detrimental environmental factors exceeds the limit values. The spatial tool makes then possible the flexible and weighted combination of the normalized indicators, by computing online the resulting composite indicator. The approach developed in the present study will be compared to other case studies and their aggregation methods by focusing on results and the possible implications on planning interventions by the decision makers.

## P02. Air Pollution 2

### **P02.0940. Short-Term Air Pollution Exposure, Residential Greenspace, Community Deprivation, and Psychiatric Emergency Visits in Children**

Cole Brokamp

*Cole Brokamp<sup>1</sup>, Patrick Ryan<sup>1</sup>*

*1. Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States.*

Abstract: Long term exposure to air pollution, residential greenspace, and community deprivation have all been independently associated with anxiety and depression in both children and adults. However, the effect of acute particulate matter less than 2.5 microns in diameter (PM<sub>2.5</sub>) exposures on psychiatric emergency department (ED) visits has not been studied in children. Our objective was to investigate the relationship between community deprivation, residential greenspace, acute PM<sub>2.5</sub>, and the risk for a psychiatric ED visit during childhood. ED visits from Cincinnati Children's Medical Hospital Center (CCHMC) between 2011 and 2015 were extracted from the electronic health record and each patient's geocoded residential address and visit date were used to assess their community deprivation (based on census tract level American Community Survey characteristics), residential greenspace (based on an address level satellite-derived normalized difference vegetation index), and individual-level exposure to daily PM<sub>2.5</sub> (based on a previously validated spatiotemporal model). We used a case control crossover study design stratified on a rolling 28-day period around the case date and day of week. Conditional logistic regression was used to estimate the odds ratio for the risk of a psychiatric ED visit 0 to 3 days after an increase in PM<sub>2.5</sub> while unconfounding for daily temperature, holidays, and within-month temporal trends. During the study period, 13,361 childhood psychiatric ED visits occurred at CCHMC. A 10 µg/m<sup>3</sup> increase in PM<sub>2.5</sub> caused an increased risk for a psychiatric ED visit one day (OR: 1.07, 95% CI: [1.02, 1.12]) and two days (OR: 1.05, 95% CI: [1.00, 1.10]) later. The effect of PM<sub>2.5</sub> was modified by community deprivation and greenspace ( $p < 0.001$ ), with children living in areas of higher deprivation being more vulnerable to the effects of PM<sub>2.5</sub>. Acute PM<sub>2.5</sub> is a modifiable exposure that causes increased morbidity associated with childhood psychiatric disorders.

## **P02.0950. Oxidative Potential of Fresh and Aged Particles from Food-Cooking Emissions**

Arthur Chan

*Manpreet Takhar<sup>1</sup>, Shunyao Wang<sup>1</sup>, Qimei Huang<sup>1</sup>, Arthur Chan<sup>1</sup>*

*1. Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, ON, Canada.*

Abstract: Particulate matter (PM) emitted from urban areas causes oxidative stress and is associated with adverse health effects. Cooking emissions represent one of the most important sources of organic PM in urban areas and have been shown to contribute 10-34% of total organic aerosol. Despite its importance, the chemical composition of fresh and aged PM from food cooking emissions and its oxidative potential (OP, or ability to cause oxidative stress) are poorly understood. In this work we use cooking oils (peanut oil, canola oil, olive oil) as a surrogate to investigate the chemical composition and its evolution upon simulated atmospheric aging. We determine the composition using thermal desorption-gas chromatography mass spectrometry (TD-GC/MS), and oxidative potential using the dithiothreitol (DTT) assay. Heated cooking oil particles were oxidised in a quartz flow tube reactor in presence of ozone or hydroxyl radicals to simulate atmospheric aging. Quartz filter samples were collected for particle-phase chemical characterization and OP evaluation. Our preliminary results show that the mass normalized OP of aged PM from cooking is similar to that of diesel exhaust particles (traffic emissions) reported in previous literature. We also observed different OPs from various types of cooking oils, among which the OP of canola oil ranks the highest. The unoxidized cooking emissions are found to be mainly comprised of saturated fatty acids ranging from C12-C20, along with palmitoleic acid, oleic acid, linoleic acid and sterols. Aged cooking emissions are comprised of dicarboxylic acids, hydroxy fatty acids, and short chain fatty acids. Overall, using oxidative potential as a screening tool, more toxicological studies are needed to understand the impact of cooking emissions on human health.

## **P02.0960. Long-Term Trends of Air Pollution in Thailand and Effects on Health**

Will Mueller

*Will Mueller<sup>1</sup>, Susanne Steinle<sup>1</sup>, Miranda Loh<sup>1</sup>, Sotiris Vardoulakis<sup>1</sup>, Nopadol Precha<sup>2</sup>, Wissanupong Kliengchuay<sup>2</sup>, Narut Sahanavin<sup>3</sup>, Ratthaphol Sillaparassamee<sup>4</sup>, Kanchana Nakhapakorn<sup>2</sup>, Kraichat Tantrakarnapa<sup>2</sup>, John Cherrie<sup>1</sup>*

- 1. Institute of Occupational Medicine, Edinburgh, United Kingdom.*
- 2. Mahidol University, Bangkok, Thailand.*
- 3. Srinakharintarawiroj University, Bangkok, Thailand.*
- 4. Nakorn Ratchasima College, Bangkok, Thailand.*

**Abstract:** Background: Air pollution is an important preventable cause of illness and disease around the world. Objective: To assess trends in the concentrations of different air pollutants in Thailand across three decades and to make a preliminary assessment of associated health impacts from prolonged exposures. Methods: We collected data from the Thai Pollution Control Department on CO, NO<sub>2</sub>, O<sub>3</sub>, PM<sub>10</sub>, PM<sub>2.5</sub>, and SO<sub>2</sub> from 68 automatic monitoring stations across Thailand, spanning the period from 1996 to 2015. We calculated annual averages of each pollutant and assessed the magnitude and direction of pollutant concentration changes over time. We will combine this historic exposure data with health data, to be provided by the Ministry of Public Health, to conduct a health impact assessment (HIA), based on longer-term exposures, of current disease burdens for select causes of mortality and morbidity. Results: Data were available for each year of the study period from 30 monitoring stations. Reductions in annual mean concentrations were observed for CO (0.88 ppm to 0.70 ppm; -20%), SO<sub>2</sub> (5.4 ppb to 2.4 ppb; -56%), and PM<sub>10</sub> (90.6 µg/m<sup>3</sup> to 44.2 µg/m<sup>3</sup>; -51%). Concentrations remained similar for NO<sub>2</sub> (15.1 ppb to 15.9 ppb; +5%) and increased for both O<sub>3</sub> (14.0 ppb to 21.2 ppb; +51%) and PM<sub>2.5</sub>, though monitoring for the latter only commenced in 2011 (22.5 µg/m<sup>3</sup> to 31.1 µg/m<sup>3</sup>; +38%). Conclusion: Preliminary analysis suggests mixed air quality trends in Thailand in recent decades. Although some improvements are apparent, there is an indication that certain pollutants, i.e., PM<sub>2.5</sub> and O<sub>3</sub>, still may be rising, which will entail adverse health consequences. For further analysis, we will complete a HIA using historic exposure trends, and, taking into account the introduction of air quality policies, we will estimate scenarios of air quality and health in the future.

**P02.0970. The Hematologic Effects Associated with Ambient BTEX Exposure among the Elderly Residents in Nanjing: A Cross-Sectional Study**

Hong Sun

*Hong Sun<sup>1</sup>, Yan Xu<sup>1</sup>, Zhen Ding<sup>1</sup>, Fangping Jiang<sup>2</sup>*

*1. environment and health, Jiangsu provincial center for disease prevention and control, Nanjing, Jiangsu, China.*

*2. Zhenjiang Municipal center for disease prevention and control, Zhenjiang, 212001, China.*

**Abstract:** Background: Previous studies suggested that occupational low-level and environmental BTEX exposure may have adverse effects on hematologic system, but the evidence is limited and inconsistent. Objective: We evaluated the exposure of indoor BTEX, blood BTEX and their potential effects on hematologic parameters of the residents from one community nearby a petrochemical complex and another in the control area; We also investigated the associations between blood BTEX and hematologic parameters. Methods: The volunteer residents were randomly recruited from one community near petrochemical complex and one community without known petrochemical pollution. Each participant accomplished a questionnaire and donated blood samples to evaluate blood BTEX concentrations and hematologic parameters. Indoor BTEX sampling was performed in 15 households of each community. We compared the data from each community, and utilized GLMs to estimate adjusted associations between blood BTEX concentrations and hematologic parameters. Results: The blood BTEX concentrations and multiple hematologic parameters of the participants were significantly different between the two study groups. The blood BTEX concentrations of the contaminated group were 1.2 to 6.7 times higher than control. Inverse associations were found between ln-transformed blood benzene concentrations and MCHC ( $\beta = -2.75$ ) and platelet counts ( $\beta = -8.18$ ). Several weaker associations were also observed between other compounds and certain hematologic parameters. Conclusions: Our results suggest that exposure to BTEX may have adverse effects on hematologic system including the diminishing concentration of MCHC, platelets, RBC counts and hemoglobin.

## **P02.0980. Association of Childhood Adversity and Increased Inflammatory Reactivity to Traffic Air Pollution**

Hector Olvera Alvarez

*Hector A. Olvera Alvarez<sup>1</sup>, Matthew Campen<sup>2</sup>, George Slavich<sup>3</sup>*

*1. School of Nursing, University of Texas at El Paso, El Paso, TX, United States.*

*2. Department of Pharmaceutical Sciences, University of New Mexico, Albuquerque, NM, United States.*

*3. Cousins Center for Psychoneuroimmunology and Department of Psychiatry and Biobehavioral Sciences, University of California Los Angeles, Los Angeles, CA, United States.*

Abstract: Socially disadvantaged individuals are at greater risk for simultaneously being exposed to severe psychosocial stress in childhood as well as poor air quality across the life span. Recent evidence from different bodies of literature suggests that severe early life stress calibrates the immune system as to increase the inflammatory response to air pollution exposure. This synergistic effect between early life stress and air pollution could contribute to disparity in diseases such as cardiovascular disease, diabetes, depression, and certain types of cancer. In this study with healthy young adults, we examined the effect of early life stress on the inflammatory response to acute non-controlled exposure to traffic related air pollution. Participants answered the adverse childhood experiences (ACE) questionnaire prior to exposure, which consisted of watching a nature documentary on television for two hours while seating in a recreational vehicle (RV) parked within 30 ft. from an interstate highway. The air inside the RV had similar air pollutant levels as those immediately outside. Levels of nitric oxide in exhaled breath (eNO) as well as serum levels of interleukin-1 $\beta$  (IL-1 $\beta$ ), interleukin-6 (IL-6), interleukin-8 (IL-8), and tumor necrosis factor alpha (TNF $\alpha$ ) were measured prior to, one hour after, and twenty-four hours after exposure. Change in inflammatory biomarker (eNO, IL-6, TNF $\alpha$ ) levels induced by air pollution as a function of ACE score was examined with "mixed" effects linear regression. Significant positive associations between ACE scores and changes in eNO levels at one-hour post exposure, as well as with IL-1 $\beta$  and IL-6 levels twenty-four hours post exposure were observed. These results were strongly influenced by sex. These results support the hypothesis that early life stress might lead to an increased inflammatory reactivity to traffic related air pollution, which in turn could drive disparity of inflammation-related health problems.

## **P02.0990. Effects of Outdoor NOx on Indoor Levels of NOx**

Rachel Golan

*Alexandra Braginsky<sup>1</sup>, Michael Friger<sup>1</sup>, David Broday<sup>2</sup>, Rachel Golan<sup>1</sup>*

*1. Department of Public Health, Ben-Gurion University of the Negev, Beer Sheva, Israel.*

*2. Faculty of Civil and Environmental Engineering, Technion, Israel Institute of Technology, Haifa, Israel.*

**Abstract:** Exposure to air pollutants increases morbidity and mortality. Traffic contributes about half of the emitted NOx to the atmosphere. Human activities play a key role in explaining exposure variation. Despite the importance of healthy air in indoor spaces, most studies focus on outdoor air. Misclassification of exposure has been recognized as a limitation of epidemiologic studies. Here we estimated the effect of outdoor traffic related air pollution on indoor air. **Methods:** Simultaneous indoor and outdoor monitoring data of pollutants were recorded during the years 2005-2007 every half hour. We examined variables associated with levels of indoor pollutant NOx( $\mu\text{g}/\text{m}^3$ ). Independent variables included outdoor levels of NOx, meteorological and seasonal factors and human related activities. In multivariate analysis, we used linear regression models and a 'Cosinor' time series technique, to examine predictors for indoor pollutants levels, adjusted for trend and seasonality. We further conducted a multivariable quantile regression analysis, adjusted for the same independent variables as the former model. **Results:** Indoor NOx level differed between weekdays and weekends ( $F=4.25$ ,  $p = 0.015$ ) and between seasons ( $F=14.56$ ,  $p<0.001$ ). Outdoor NOx was the main predictor for indoor NOx levels ( $\beta=0.67$ ,  $p<0.001$ ). In multiple linear regression analysis adjusted for linear trend ( $\beta= 0.134$ ,  $p<0.001$ ), season (winter  $\beta=-1.40$ ,  $p<.001$ , summer  $\beta=0.628$ ,  $p=0.224$ , fall  $\beta=-0.09$ ,  $p=0.83$ , compared to spring), outdoor NOx ( $\beta=-0.81$ ,  $p=.001$ ), temperature ( $\beta=-0.75$ ,  $p=.028$ ) rainfall ( $\beta=-0.50$ ,  $p=.006$ ), relative humidity ( $\beta=0.42$ ,  $p=0.03$ ) wind speed ( $\beta=0.41$ ,  $p=0.01$ ) were associated with indoor NOx levels. **Conclusions:** Our findings contribute to a growing body of literature describing the relationships between indoor and outdoor of traffic related air pollutants. Further understanding the extent of the effect of indoor air on health is essential especially when considering the amount of time people spend indoors.

## **P02.1000. Exposures to Traffic-Related Air Pollutants are Associated with Changes in Amino Acid Metabolism**

Zhanghua Chen

*Zhanghua Chen<sup>1</sup>, Douglas I. Walker<sup>2</sup>, Jeniffer Kim<sup>1</sup>, Tanya Alderete<sup>1</sup>, Leda Chatzi<sup>1</sup>, Dean Jones<sup>2</sup>, Miguel Pereira<sup>1</sup>, David Conti<sup>1</sup>, Duncan Thomas<sup>1</sup>, Elizabeth Hauser<sup>3</sup>, Frank Gilliland<sup>1</sup>*

*2. Department of Medicine, Emory University, Atlanta, GA, United States.*

*3. Duke Molecular Physiology Institute, Duke University, Durham, NC, United States.*

**Abstract:** Air pollutants (AP) exposures have been associated with increased risk of cardiometabolic diseases; however, the exact mechanism is unclear. In this study, we examined the association between AP exposure and changes in serum metabolite levels using non-targeted metabolomics. A total of 104 participants in southern California (age 18-21 years) were included in this analysis. Of these participants, 56.7% were male, 48.1% were Hispanic White and 39.4% were non-Hispanic White. Ambient air pollutant exposures were collected from central monitors, and traffic-related air pollutants (NO<sub>x</sub>) from freeway/non-freeway sources were estimated by a line dispersion model using home and school addresses. Annual averaged exposure to AP was calculated from monthly concentrations for the year prior to the study visit. Non-targeted, high-resolution metabolomics was analyzed using fasting serum samples. After excluding metabolomics features with >50% missing data, intensities of 13,559 features were detected. After data pre-processing, associations of AP exposures with metabolomic features were examined by linear regression adjusting for age, sex, ethnicity, parental education and body mass index. Significant metabolites were used to create metabolic pathways by pathway enrichment analyses. We found increased exposure to PM<sub>2.5</sub> and non-freeway NO<sub>x</sub> were associated with changes in arginine and proline metabolism ( $p < 0.001$ ) and  $\beta$ -alanine metabolism ( $p = 0.03$ ), suggesting AP-induced oxidative stress. Increased PM<sub>2.5</sub> exposure was also associated with branched-chain amino acids catabolism ( $p = 0.01$ ), which is known to increase diabetes risk. Additionally, increased NO<sub>2</sub> exposure was associated with phenylalanine, tyrosine and tryptophan biosynthesis ( $p < 0.001$ ), indicating activation of stress pathways. In summary, AP exposure, especially from traffic sources, was associated with changes in amino acid metabolism that could further contribute to the development of cardiometabolic diseases.

## **P02.1010. A New Method to Estimate the Health Effect of Mixtures of Ozone, Nitrogen Dioxide, and Fine Particulates in 85 U.S. Counties**

Jia Liu

*Jia C. Liu<sup>1</sup>, Roger Peng<sup>1</sup>*

*1. Biostatistics, Johns Hopkins University, Baltimore, MD, United States.*

**Abstract:** Background: Despite substantial improvements in ambient air quality in the past decades, ozone (O<sub>3</sub>), nitrogen dioxide (NO<sub>2</sub>), and fine particulate matter (PM<sub>2.5</sub>) remain as concerns. As these pollutants exist as mixtures in ambient environments, some combinations of these pollutants may be more harmful to human health than other combinations. Identifying harmful pollutant mixtures can help develop multi-pollutant control strategies to better protect health. Current methods exhibit limitations in identifying harmful mixtures. We aim to identify harmful compositions of three-pollutant mixtures in 85 US counties during 1999-2010. Methods: We developed a new method called PANCAKE to quantify O<sub>3</sub>-NO<sub>2</sub>-PM<sub>2.5</sub> mixtures. O<sub>3</sub>-NO<sub>2</sub>-PM<sub>2.5</sub> mixtures are categorized into 27 composition types based on combinations of different O<sub>3</sub>, NO<sub>2</sub>, and PM<sub>2.5</sub> levels. We identified harmful compositions by estimating the effect of each composition of O<sub>3</sub>-NO<sub>2</sub>-PM<sub>2.5</sub> mixture compared to the reference composition on cardiovascular admissions among Medicare patients. Results: We found that a mixture with relatively low levels of some pollutants combined with relatively high levels of other pollutants can be equally or more harmful than a mixture with high levels of all pollutants. Eight out of the 27 composition types, often with NO<sub>2</sub> levels > 17.3 ppb and PM<sub>2.5</sub> levels > 8.8 µg/m<sup>3</sup> combined with any levels of O<sub>3</sub>, were associated with significantly increased cardiovascular admission rates compared to the reference composition. These harmful compositions overall occurred in about 40-50% of days in winter, metropolitan areas, or the East North Central region. Conclusion: Mixture composition plays an important role in determining health risks and may be worth considering when developing air pollution control strategies.

**P02.1020. An LPW Estimate of the Effects of Annual Exposure to PM2.5 and Ozone on Hospital Admission Rates of Medicare Participants in the Southeast U.S.A.**

Joel Schwartz

*Mahdieh Danesh-Yazdi<sup>1</sup>, Yan Wang<sup>1</sup>, Qian Di<sup>1</sup>, Antonella Zanobetti<sup>1</sup>, Joel D. Schwartz<sup>1</sup>*

*1. Environmental Health, Harvard University, Boston, MA, United States.*

**Abstract:** Introduction: Air pollution is associated with hospital admissions, but few studies have examined the long-term effects of PM2.5 and ozone, or at low concentrations. Existing studies do not use causal modeling or account for the competing risk of death. Methods: We fit a marginal structural Cox proportional hazards model, using stabilized inverse probability weights (IPWs) to account for the competing risk of death and confounding. We examined the association between average annual fine particulate matter (PM2.5) and ozone and first hospital admissions of Medicare participants in the southeast US for stroke, chronic obstructive pulmonary disease (COPD), pneumonia, myocardial infarction (MI), lung cancer, and heart failure (HF). Analyses were then restricted to levels below the current U.S. standard: Average annual measurements of PM2.5 below 12 µg/m<sup>3</sup> and zip codes and years in which ozone levels were below 70 parts per billion (ppb) on all days. Results: PM2.5 was significantly associated with an increased hazard of admissions for all studied outcomes; the highest observed being a 6.1% (95% CI: 6.0%- 6.2%) increase in admissions for pneumonia for each µg/m<sup>3</sup> increase in PM2.5. When the analysis was restricted to observations with PM2.5 levels below 12 µg/m<sup>3</sup> we found an increase of 10.2% (95% CI: 9.8%-10.6%). For all causes, the restriction resulted in a higher marginal increase in admissions for that outcome. Ozone was also significantly associated with an increase in the risk of first hospital admissions of all outcomes. The hazard of pneumonia increased by 3.0% (95% CI: 2.9%-3.1%) for each ppb increase in ozone. The estimated effect sizes were well above those reported for short-term exposure. Conclusion: Long-term PM2.5 and ozone exposures are associated with increased rates of hospital admissions for a number of serious illnesses. Our results indicate a need to regulate long-term ozone exposure, and that associations persist below current US PM2.5 standards.

## **P02.1030. Air Pollution and the Modification by Spatial Synoptic Classification on Mortality**

Jayeun Kim

*Jayeun Kim<sup>1</sup>, Ho Kim<sup>2</sup>*

- 1. Institute of Health and Environment, Seoul National University, Seoul, Korea (the Republic of).*
- 2. Graduate School of Public Health, Seoul National University, Seoul, Korea (the Republic of).*

**Abstract:** Background Korean Peninsula has the distinct seasonal characteristics and the study on seasonality is relatively frequent compared to the relationship with synoptic classification (SSC). In the study, we aimed to investigate the modification effect between air pollution and SSC on mortality. Methods Daily death data were collected through the Korean Statistics between 2000 and 2014 in Seoul, Korea. We conducted the time-series study using Poisson generalized linear models with an allowance of over-dispersion with seven distinctive SSC (Dry moderate [DM], Dry polar [DP], Dry tropical [DT], Moist moderate [MM], Moist polar [MP], Moist tropical [MT], and Transition [T]) and investigated the modification effects between the SSC and PM10 adjusting for other meteorological conditions, and time trend. The estimated effects were expressed as percentage changes in the risk with 95% confidence interval (CI) per interquartile range(IQR) increase in PM10 for daily non-accidental, cardiovascular-, respiratory-related mortality associated with exposure to PM10 at lag 0–4 according to the type of SSC. Results Daily PM10 level was greater in days [DM] (mean, 61.0  $\mu\text{g}/\text{m}^3$ ) and [DT] (mean, 61.8  $\mu\text{g}/\text{m}^3$ ) and the overall risk of mortality increase were observed in non-accidental [1.11% (95% CI 0.50%, 1.73%)], and cardiovascular [1.87% (95% CI 0.68%, 3.08%)] for PM10 IQR increase. In addition, we observed the mortality risk modified by SSC and increased effect was observed in [DM], [DT], [MM], [MT], and [T] in non-accidental and cardiovascular-related mortality. In particular, we observed the increased risk in [MT] regardless cause of death with non-accidental [1.86% (95% CI 1.02%, 2.70%)], cardiovascular [2.01% (95% CI 0.37%, 3.67%)], and respiratory [3.78% (95% CI 0.89%, 6.76%)]. Discussion the application of SSC in the investigation of air pollution and short-term health effects assisted to understand the health risks in overall weather condition.

## **P02.1040. Seasonal Analyses of the Association between Prenatal Ambient Air Pollution Exposure and Abnormal Birth Weight in Guangzhou, China**

Qiong Wang

*Qiong Wang<sup>1</sup>, Tarik Benmarhnia<sup>2</sup>, Changchang Li<sup>1</sup>, Luke Knibbs<sup>3</sup>, Men Ren<sup>1</sup>, Huanhuan Zhang<sup>1</sup>, Yawei Zhang<sup>4</sup>, Cunrui Huang<sup>1</sup>*

- 4. School of Public Health, Yale University, New Haven, CT, United States.*

**Abstract:** Ambient air pollution has been linked to small for gestational age (SGA). However, the relationship between air pollution and large for gestational age (LGA) is unclear and very few study has investigated seasonal impact on the association between air pollution and SGA/LGA. Using data from the Guangzhou Birth Registry including 506,000 singleton live births between January 2015 and July 2017, we examined associations between ambient air pollutants and risk of SGA/ LGA, and whether the association varied by season. Daily average concentrations of PM<sub>2.5</sub>, PM<sub>10</sub>, NO<sub>2</sub>, SO<sub>2</sub>, and O<sub>3</sub> from 11 monitoring stations were used to estimate district-specific exposures for each participant based on residential addresses during pregnancy. Two-level binary logistic regression models were used to evaluate associations between air pollution and SGA/LGA, controlling for temperature, seasonality, and individual covariates. Stratified analyses by season were performed to assess the modification of season on effects of air pollution. Exposure to PM<sub>2.5</sub>, NO<sub>2</sub>, SO<sub>2</sub>, and O<sub>3</sub> was associated with increased risk of SGA, especially for exposure during late pregnancy. Stronger effects were observed for NO<sub>2</sub> and O<sub>3</sub>. For an IQR increase in exposure to NO<sub>2</sub> (12.7 µg/m<sup>3</sup>) or O<sub>3</sub> (21.3 µg/m<sup>3</sup>) during the entire pregnancy, SGA risk increased by 8% (OR=1.08, 95% CI: 1.04-1.12) and 13% (OR=1.13, 95% CI: 1.10-1.15), respectively. When examined by season, significant associations between air pollutants and SGA were observed for women who conceived during summer or fall, and the patterns were consistent for all pollutants. Exposure to NO<sub>2</sub> during the entire pregnancy increased the risk of LGA (OR=1.05, 95%CI: 1.03-1.08), however, exposure to other pollutants was associated with reduced risk of LGA. Our results suggest that conception during different season might modify the association between ambient air pollution and SGA. The novel finding that NO<sub>2</sub> exposure increases the risk of LGA warrants further investigation.

## **P02.1050. The Body Response Time in Air Pollution on the Risk of Arrhythmia Symptom Exacerbation**

Jayeun Kim

*Jayeun Kim<sup>1</sup>, Ho Kim<sup>2</sup>*

- 1. Institute of Health and Environment, Seoul National University, Seoul, Korea (the Republic of).*
- 2. Graduate School of Public Health, Seoul National University, Seoul, Korea (the Republic of).*

**Abstract:** Objectives The body response time and an association between the exposure to air pollution level and cardiac arrhythmia were not fully understood. Hence, we investigated relationship between air pollutant levels with arrhythmia symptom exacerbation at an hourly timescale including modification by spatial synoptic classification (SSC) and demographic factors. Methods In this study conducted in Seoul, Korea in 2008-2011, arrhythmia-related emergency department (ED) visits were correlated with hourly data on particulate matter (PM) and ozone (O<sub>3</sub>) concentrations under the case-crossover analysis with the same year-month time stratification. The lag between an interquartile range increase in pollutant concentration and arrhythmia exacerbation was stratified as every 6 hours within 24 hours. Effect size [odds ratio (OR), 95% confidence interval (CI)] of increased pollutant levels on ED visits was analyzed according to SSC for the modification effect. In addition, gender, age, and socio-economic status (SES), in single- and multi-pollutant models after adjusting for meteorological variables. Measurements and Main Results Of 17,088 arrhythmia-related ED visits, 9,316 (54.5%) were by men, 8,189 (47.9%) by 20-64 year olds, and 16,114 (94.3%) by high SES patients. The highest adverse effect [OR, (95% CI)] was of 10 µm diameter PM (PM<sub>10</sub> after 1-6 h [1.03, (1.00-1.05)]), and of PM<sub>10-2.5</sub>, after 7-12 h [1.04, (1.00-1.08)] and the effect were stayed up to 19-24 h [1.04, (1.00-1.08)]. Effect of O<sub>3</sub> was age-modified with increased effect for the elderly greater than 65 years and the effect of PM and O<sub>3</sub> was modified by SSC with adverse effect in dry moderate [DM] after 1-6 h. Conclusions Increased PM and O<sub>3</sub> levels lead to increased risk of arrhythmia exacerbation and modified by the demographic factors and the type of SSC after adjusting meteorological variables.

## **P02.1060. Assessment of Personal Exposure to Near-Road PM2.5 Combining Measurements and Modelling Data**

Abstract: Epidemiological studies have revealed significant associations between personal exposure to PM2.5 and adverse human health effects, in particular on the respiratory and cardiovascular systems. In urban areas, motor vehicles are significant sources of PM2.5 emissions. Although periods of personal exposure to PM2.5 outdoors are relatively short on a daily time scale, high acute exposure occurs during daily commutes. To estimate personal exposure to near-road PM2.5, a modelling system is proposed that integrates a traffic-emissions simulator, an atmospheric transport model and an exposure-inhalation model. PM2.5 inhalation concentrations are estimated for a cohort of male and female adults, and children at age 6 and 10 during cycling, running, walking, commuting and rest near-roads. Results show that PM2.5 inhalation is strongly correlated with exposure periods and physical activities. Adults exhibit higher PM2.5 inhalation than children due to higher respiratory rates for all physical activities considered. However, all personal profiles evaluated show that PM2.5 inhalation may increase between 1.5 to 5 times during morning and evening traffic rush hours compared with periods of lower traffic volume flow. Significant increases in inhalation are observed close to PM2.5 hot-spots such as road intersections, traffic light signs and traffic calming devices. This methodology identifies spatio-temporal critical areas near schools, hospitals, sport fields and other venues where susceptible receptors are highly exposed. The modelling system allows vehicle engine and emission technologies to be tested, and pedestrian and cycling routes to be chosen to minimise personal exposure.

## **P02.1070. A Community Driven Initiative to Investigate the Health Impacts of Exposure to Outdoor Air**

Paleah Moher

*Paleah Moher<sup>1</sup>, Kristian Larsen<sup>1</sup>, Alison Palmer<sup>1</sup>, Heather Robertson<sup>2</sup>, Sara Plain<sup>3</sup>, Kayley Henning<sup>2</sup>, Sehar Jama<sup>2</sup>, Amanda Sheppard<sup>2</sup>*

- 3. Health Services, Aamjiwnaang First Nation, Sarnia, ON, Canada.*

Abstract: Aamjiwnaang First Nation is situated near the Sarnia-Lambton "Chemical Valley", an industrial complex of refining and chemical companies, with poor air quality, chemical spills and other environmental events. Residents of Aamjiwnaang are concerned about the health impacts of these environmental exposures. In past decades, Aamjiwnaang has been involved in approximately 20 environmental and health research studies. The aim of this project is to consolidate these data to describe a more complete account of exposure, in collaboration with the Health Committee at Aamjiwnaang to integrate academic tools with Indigenous knowledge. This initiative has three components: 1) a screening-level cancer risk assessment on the community's exposure to outdoor air; 2) a systematic review of the impact of environmental factors on health; 3) digital stories to portray community members' perspectives. We investigated current (2015-2016) and historical (1995-1996, 2005-2006) data from four nearby air monitoring stations to assess outdoor air exposures and to map air concentrations in the Sarnia area. The assessment found that air concentrations of several pollutants, including benzene, are improving overtime, however for all years investigated benzene levels are above the ambient air quality control (AAQC) target, which are set by Ontario's Ministry of Environment and Climate Change (MOECC). The concentrations of several pollutants, including benzene, were higher in Sarnia than provincial annual averages. The systematic review of the peer-reviewed literature found that there was evidence of exposure to environmental pollutants in this community. This work will contribute to an enhanced understanding of environmental impact on health among Aamjiwnaang residents, and highlights the importance of partnership to create actionable recommendations and products for First Nations communities.

## **P02.1080. The Association of Traffic-Related Air and Noise Pollution with Maternal Blood Pressure in the HOME Study**

Clara Sears

- 6. Faculty of Health Sciences, Simon Fraser University, Burnaby, BC, Canada.*

**Abstract:** Background: Traffic-related air and noise pollution may increase the risk for cardiovascular disorders, especially among vulnerable populations like pregnant women. Objective: To evaluate the association of exposure to elemental carbon attributable to traffic (ECAT, a marker of traffic-related air pollution) and traffic noise with maternal blood pressure. Methods: Systolic blood pressure (SBP) and diastolic blood pressure (DBP) measurements at >20 weeks gestation were assessed in the HOME Study, a prospective pregnancy and birth cohort from Cincinnati, OH (n=350). At women's residential address during pregnancy we estimated ECAT exposure using a validated land use regression model and roadway noise using a publicly available transportation noise model. We used linear mixed models to assess associations of blood pressure with ECAT and traffic noise after adjusting for covariates and early pregnancy blood pressure. Results: Women living in census tracts of lower neighborhood socioeconomic status were exposed to higher ECAT concentrations and were more likely to be exposed to traffic noise >35 dBA. Women in the highest versus lowest ECAT tercile had statistically significantly higher SBP in late pregnancy (2.8 mmHg, 95%CI=0.0, 5.5; p=0.047); the association was stronger after adjusting for traffic noise (3.1 mm Hg, 95%CI= 0.3, 5.9; p=0.030). Traffic noise was not independently associated with SBP or DBP, and ECAT was not associated with DBP. Additionally, there was no evidence of a joint effect of traffic noise and ECAT on blood pressure. Conclusion: In this cohort, estimated residential ECAT at ~20 weeks gestation was associated with higher SBP in late pregnancy. Future studies of traffic-related air or noise pollution should consider jointly adjusting for both exposures and neighborhood characteristics due to their correlations and potential associations with cardiovascular disorders.

## **P02.1090. Air Pollution, Land Use, and Complications of Pregnancy**

**Abstract:** Mounting evidence suggests that the natural and built environment can affect human health, but relatively few studies have considered links between features of the residential natural and built environment other than air pollution and complications of pregnancy. To quantify the impact of features of the maternal residential natural and built environments on risk of gestational diabetes mellitus (GDM), gestational hypertension and preeclampsia among 61,640 women who delivered at a single hospital in Rhode Island between 2002 and 2012. We estimated residential levels of ambient fine particulate matter (PM<sub>2.5</sub>) and black carbon (BC) using spatiotemporal models, neighborhood green space using remote sensing and proximity to recreational facilities, and neighborhood blue space using distance to coastal and fresh water. We used logistic regression to separately estimate the association between each feature and GDM, gestational hypertension, and preeclampsia, adjusting for individual and neighborhood markers of socioeconomic status. GDM, gestational hypertension, and preeclampsia were diagnosed in 8.0%, 5.0%, and 3.6% of women, respectively. We found 2nd trimester PM<sub>2.5</sub> (OR=1.08, 95% CI: 1.00, 1.15 per interquartile range increase in PM<sub>2.5</sub>) and living close to a major roadway (1.09, 95% CI: 1.00, 1.19) were associated with higher odds of GDM, while living <1km from the coast was associated with lower odds of GDM (0.87, 95% CI: 0.78, 0.96). Living <500m from a recreational facility was associated with lower odds of gestational hypertension (0.89, 95% CI: 0.80, 0.99). None of these features were associated with preeclampsia. Results were qualitatively similar in mutually-adjusted models and sensitivity analyses. In this medium-sized coastal US state, risk of GDM was positively associated with PM<sub>2.5</sub> and proximity to busy roadways, and negatively associated with proximity to blue space, highlighting the importance of the natural and built environment to maternal health.

## **P02.1110. Air Pollution Exposure and Risk of Spontaneous Abortion in the Nurses' Health Study II**

Audrey Gaskins

*Audrey J. Gaskins<sup>1</sup>, Jaime E. Hart<sup>1</sup>, Jorge E. Chavarro<sup>1</sup>, Stacey A. Missmer<sup>2</sup>, Janet W. Rich-Edwards<sup>1</sup>, Francine Laden<sup>1</sup>, Shruthi Mahalingaiah<sup>3</sup>*

*3. Boston University School of Medicine, Boston, MA, United States.*

**Abstract:** Background/Aim: A growing literature suggests that air pollution adversely affects early pregnancy outcomes, particularly pregnancy loss; however the evidence is limited. The objective of this study was to examine whether air pollution exposures are associated with risk of spontaneous abortion (SAB). Methods: Our prospective cohort study included 19,309 women in the Nurses' Health Study II who contributed a total of 35,025 pregnancies between 1990 and 2008. Proximity to major roadways and exposure to particulate matter <10 microns (PM<sub>10</sub>), 2.5-10 microns (PM<sub>2.5-10</sub>), and <2.5 microns (PM<sub>2.5</sub>) were determined for residential addresses between 1989 and 2007. Multivariable log-binomial regression models with generalized estimating equations were used to estimate the risk ratios (RRs) and 95% confidence intervals (CIs) of SAB. We also conducted a bidirectional case-crossover analysis among 3,693 women (11,805 pregnancies) with at least one SAB and at least one control pregnancy during follow-up using conditional logistic regression. Results: During the 19 years of follow-up, 6599 SABs (18.8%) were reported. In the main analysis, living closer to a major roadway and average exposure to PM<sub>10</sub>, PM<sub>10-2.5</sub>, or PM<sub>2.5</sub> in the year prior to pregnancy were not associated with an increased risk of SAB. However, in the case-crossover analysis, each 10 µg/m increase in PM<sub>10</sub>, PM<sub>2.5-10</sub>, and PM<sub>2.5</sub> in the year prior to pregnancy was associated with 1.27 (95% CI 1.11, 1.46), 1.35 (95% CI 1.09, 1.66), and 1.51 (95% CI 1.15, 1.97) higher odds of SAB, respectively. Conclusion: Higher exposure to air pollution within a woman in the year prior to pregnancy may be associated with increased risk of SAB.

## **P02.1120. Exploring Association of Long-Term Ultrafine Particle Exposure with IL-1 $\beta$**

Doug Brugge

*Doug Brugge<sup>1</sup>, Maureen McGill<sup>1</sup>, Wig Zamore<sup>2</sup>, Kevin J. Lane<sup>3</sup>*

- 1. Public Health, Tufts University, Boston, MA, United States.*
- 2. Somerville Transportation Equity Partnership, Somerville, MA, United States.*
- 3. Boston University School of Public Health, Boston, MA, United States.*

**Abstract:** Introduction: Traffic related ultrafine particles (UFP) are increasingly reported to be associated with adverse health outcomes and biomarkers of sterile inflammation. IL-1 $\beta$  is a core driver of inflammation that is a product of activation of the inflammasome. IL-1 $\beta$  has been associated with exposure to other sizes of particulate matter which led us to explore associations with UFP. Methods: We analyzed plasma samples stored at -80°C from the Community Assessment of Freeway Exposure and Health study (CAFEH; N=389). Samples were assayed for IL-1 $\beta$  by ELISA using the Quantikine HS Human IL-1 beta Immunoassay. Individual UFP exposure had previously been assigned to these participants as time activity adjusted particle number concentration (TAA-PNC). Annual average exposure ranged from 9,000 - 35,000 particles/cm<sup>3</sup>. The majority of participants (54%) had an IL-1 $\beta$  below the LOD (0.125 pg/mL), therefore we dichotomized IL-1 $\beta$  to over or under the LOD and conducted logistic regression analysis adjusting for age, gender, BMI, race and smoking status. We also conducted a generalized linear regression analysis for associations in participants with a value above the LOD. Results: TAA-PNC was associated with IL-1 $\beta$  in our adjusted logistic regression model. For every 1,000 particles/cm<sup>2</sup> increase in exposure there was a 4% (95%CI: 0.4%, 7.3%) increase in the odds of having a detectable level of IL-1 $\beta$ . We found no meaningful association of TAA-PNC with IL-1 $\beta$  using generalized linear regression analysis. Conclusions: We found some evidence of an association of UFP with plasma IL-1 $\beta$  levels, however further research is needed.

**Abstract:** Outdoor fine particulate matter (PM<sub>2.5</sub>) air pollution is a major cause of death in the United States. We explore the relationships among PM<sub>2.5</sub> health impacts, sources of the responsible emissions, and the economic demand that induces those emissions. We create a spatially-explicit environmentally-extended economic input-output model for the United States by coupling economic input-output and consumption data with spatially-explicit emissions data, a reduced-complexity air quality model, and spatially-explicit population and health data. The resulting model relates air pollution emissions, concentrations, and health impacts with economic activity in the United States at a spatial scale varying between 1 and 48 km (depending on population density). We find that of 180,000 air quality-related mortalities in year-2014, 75% were induced by economic demand. Individuals identifying as Black or African-American and Hispanic or Latino were exposed to 65% more personal-consumption-induced PM<sub>2.5</sub> than what would be equitable given their level of personal consumption. Between 1997 and 2015, reductions in emissions per unit production reduced demand-related air pollution mortalities by 35% despite increasing population and per-capita economic consumption; corresponding race-ethnicity inequity has decreased more slowly.

**P02.1150. Cardiovascular Mortality Reductions Related to Improved Air Quality Vary by Socioeconomic Status: A Moderated Mediation Analysis**

Lauren Wyatt

*1. ORISE / US Environmental Protection Agency, Chapel Hill, NC, United States.*

*2. US Environmental Protection Agency, Chapel Hill, NC, United States.*

**Abstract:** Background: Chronic air pollution exposure is a risk factor for cardiovascular disease (CVD) and recent work suggests that CVD mortality reduction over time is partially attributed to improved air quality. We assessed the extent that mortality reduction via PM<sub>2.5</sub> change varies by county characteristics and focused on socioeconomic (SES) variables (income, poverty, and unemployment), initial air pollution and sources, employment by sector, and built environment. Methods: Data for 2,132 US counties between 1990 and 2010 included annual age standardized mortality rates from the US National Center for Health Statistics, annual average PM<sub>2.5</sub> concentrations from the US Environmental Protection Agency's Community Multiscale Air Quality (CMAQ) modeling framework, baseline SES, and county urbanization level (metropolitan, metro; non-metropolitan, non-metro). A moderated mediation analysis using weighted linear models measured how the indirect effect on CVD mortality via PM<sub>2.5</sub> is moderated by county SES status and urbanization level. Average mediation at different levels of SES were estimated from bootstrap replications. Results: In a preliminary analysis, SES moderated the PM<sub>2.5</sub>-mediated cardiovascular trend differently in metro and non-metro counties. Trends in annual PM<sub>2.5</sub> reduction and the health benefit (mortality reduction) per 1 microgram PM<sub>2.5</sub> by SES status were similar between metro and non-metro counties. PM<sub>2.5</sub> reductions were greatest in counties with higher income, lower poverty, and lower unemployment, while the largest health benefits were observed in counties with lower SES status. In metro counties, PM<sub>2.5</sub> mediation was moderated by county poverty level, with increased mediation in counties with greater poverty. In non-metro counties, mediation via PM<sub>2.5</sub> was consistent for all poverty levels. Conclusions: We identified that PM mediated health benefits were greatest in metropolitan counties with greater SES status. This abstract does not reflect EPA policy.

**P02.1160. Source Specific-PM2.5 Associated with Heart Rate Variability in Elderly Adults with Coronary Diseases: A Community-Based Panel Study**

Xi Chen

*Xi Chen<sup>1</sup>, Dongqun Xu<sup>1</sup>*

*1. National Institute of Environmental Health, Chinese Center for Disease Control and Prevention, Beijing, Beijing, China.*

**Abstract:** Background: Heart rate variability(HRV) is an important predictor of cardiovascular disease, and evidence for an association between ambient particulate matter exposure and HRV is increasing, but little is known about the relative contribution of various sources and toxicity of particle components. Objective: To compare short-term effects of fine particulates (PM2.5) from different sources on the HRV and blood levels of C-reactive protein (CRP). Methods: HRV and CRP levels were measured at monthly clinic visits in panels of elderly subjects with coronary heart disease from Gaojing community in east Beijing in early 2017. 24 patients were followed for 4 months and the visits of every subjects were always scheduled for the same weekday. Daily outdoor levels of PM2.5 and its related chemical components were measured at one central site within the community and personal time-activity patterns information was collected concurrently with the visits. PM2.5 was identified between main sources using positive matrix factorization. The individual exposures were estimated through micro-environmental model. We linked source-specific PM2.5 with HRV and CRP levels using mixed model to evaluate the toxicity of particle components for cardiovascular effects of PM. Results:pNN50 and rMSSD as sensitivity indicators were filtered and lagging effects of exposure to PM2.5 and PM2.5-Pb were observed. By comparing diverse models, it confirmed that the estimates for health effects of lag6 to lag3 exposure to PM2.5 and related chemical components were significantly different. For pNN50, exposure to PM2.5 could cooperate with the effect of temperature on cardiovascular health. When controlling exposures to PM2.5 and PM2.5-Pb, protective effects of Beta-blocker use on cardiovascular health were observed. Conclusions: Our results suggest that differences in the components of particles, Beta-blocker use, and gender of study subjects may explain some inconsistencies among previous studies on HRV.

**P02.1170. Geographically Varied Associations between Hypertensive Disorders in Pregnancy and Particulate Matter in the Contiguous United States, 1999-2004**

Tao Xue

*Tao Xue<sup>1</sup>, Tong Zhu<sup>1</sup>, Weiwei Lin<sup>2</sup>, Evelyn Talbott<sup>3</sup>*

Abstract: Hypertensive disorders in pregnancy harm both maternal and infant health and have been linked to ambient particulate matter (including PM<sub>2.5</sub> and PM<sub>10</sub>). However, existing studies are restricted to a local-scale and remain inconsistent. A large-scale study is required to enrich the epidemiological evidence and explore the potential sources of the inconsistency. Making use of United States birth certificates (1999-2004), and monitoring data from the environmental protection agency air quality networks, we associated hypertensive disorders in pregnancy with maternal exposure to PM<sub>2.5</sub> or PM<sub>10</sub> using logistic regression analysis after adjusting for many covariates among more than 5 million subjects in the contiguous United States. Additional analyses were conducted to examine variations in the associations according to: (1) Census divisions; (2) Individual-level factors; (3) A socioeconomic indicator, county-level poverty; and (4) The concentration of ambient particles. The results indicated that hypertensive disorders in pregnancy was robustly linked to maternal exposure to PM<sub>2.5</sub> with an adjusted odds ratio of 1.10 (95% confidence intervals, 1.08-1.12) per 5 µg/m<sup>3</sup> increment in terms of the entire-pregnancy mean. Stronger associations were found among white mothers. There were also considerable variations in the association by census division or poverty level among counties. Nonlinear analysis indicated a sublinear dose-response function with a threshold concentration of 9 µg/m<sup>3</sup>. Based on the national study, we calculated the population attributable fractions and found that 8.1% (6.8%-9.4%) of hypertensive disorder cases were attributable to an entire-pregnancy exposure of PM<sub>2.5</sub>. These findings can help policymakers to plan related interventions.

## **P02.1180. Assessing Determinants of Sustained Fuel Transitions.**

**Abstract:** Solid fuel combustion remains a dominant energy source for household heating and cooking in low- and middle-income countries. As a result, almost three billion people are exposed to indoor air pollution, causing four million premature deaths annually, primarily among poor women and children. We analyze Demographic and Health Surveys from 69 countries, in combination with data from the World Bank (World Development Indicators) and the United Nations (energy production data) to identify variables associated with successful fuel transitions. We evaluate cross-country variation in solid fuel use using population-average linear regression in a series of models: Population, Socio-economic, Political, Energy, and Pooled models. The pooled model shows that population density, population size, rural population share, income inequality, and charcoal production are positively associated with countries' solid fuel use, while GDP per capita, electricity production, and natural gas production have a negative relationship with solid fuel use. Economic development (GDP per capita) is the most substantively significant variable for predicting solid fuel use: A standard deviation increase in per capita GDP above its mean reduces solid fuel use from 70.2% to 57.1% of households. Population size is another strong predictor: solid fuel use rises from 70.2% to 78.8% when population size increases by one standard deviation above the mean. Finally, using fixed-effects linear regression, we estimate within-country changes in solid fuel use with time. In the pooled model, increasing population size is related to increases in solid fuel use, while increases in GDP per capita and the presence of government programs promoting renewable energy lead to a reduction in solid fuel use. Identifying evidence-based factors that foster clean fuel transitions is expected to inform improvements in indoor air quality, thereby benefitting public health and reducing mortality and morbidity.

## **P02.1190. Characterizing Personal Fine and Ultrafine Particle Exposures among Inner-City Children with Asthma**

Ehsan Majd

*Ehsan Majd<sup>1</sup>, Meredith McCormack<sup>2</sup>, Nadia Hansel<sup>2</sup>, Kirsten Koehler<sup>1</sup>*

*1. Environmental Health and Engineering, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD, United States.*

*2. Pulmonary and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, United States.*

**Abstract:** The PEAK study aims to determine the association of particle size, microenvironment (ME) and peak exposure with respiratory effects in children with asthma. 25 children aged 8-17 with asthma were each followed for 4 consecutive days. Children's personal PM<sub>2.5</sub> (particles with diameter less than 2.5  $\mu\text{m}$ ) and ultrafine particle (UFP, diameter less than 0.1  $\mu\text{m}$ ) exposures were measured at high spatiotemporal resolutions using a backpack containing personal PM<sub>2.5</sub> and UFP (expressed as LDSA, lung-deposited surface area) monitors and a GPS for geographic location (logging interval= 10 seconds). Information about means of transportation used, places visited, and activities at home that may have resulted in high exposures were also obtained. Exposures were partitioned into five MEs: Home, School, Vehicle transport, Pedestrian transport, and Other. PM<sub>2.5</sub> and UFP cumulative exposures were dominated by Home. Mean UFP exposure intensities while in Pedestrian transport and Vehicle transport were both greater than 1 and higher than PM<sub>2.5</sub>. Exposure intensities while in Pedestrian transport were also greater than Vehicle transport. Correlations between PM<sub>2.5</sub> and LDSA concentrations were examined to evaluate the need for personal UFP exposure monitoring in addition to the commonly-monitored PM<sub>2.5</sub>. The highest and lowest mean PM<sub>2.5</sub>/LDSA correlation coefficients belonged to Home ( $r=0.47$ ) and Vehicle transport ( $r=0.15$ ). Home pollutant correlations were particularly weak (high UFP and low PM<sub>2.5</sub>) during evening hours and coincided with common household activities such as cooking, cleaning, and burning candles/incense. Our findings suggest that UFP exposure is only weakly to moderately correlated with fine PM exposure, suggesting that personal exposure monitoring at high spatiotemporal resolutions and including UFP to personal exposure monitoring campaigns, may be important to fully understand the effect of particulate exposures in susceptible populations such as children with asthma.

## **P02.1200. Household Air Pollution and Arthritis in Low- and Middle-Income Countries: Evidence from the World Health Organization's Study on Global Ageing and Adult Health**

Shelby Yamamoto

*Shelby Yamamoto<sup>1</sup>, Elaine Yacyshyn<sup>2</sup>, Gian Jhangri<sup>1</sup>, Arvind Chopra<sup>3</sup>, Divya Parmar<sup>4</sup>, Allyson Jones<sup>5</sup>*

Abstract: Evidence points to a clear link between air pollution exposure and several chronic diseases. However, investigations regarding arthritis are still lacking. Ambient air pollution and smoking have been associated with a higher risk of rheumatoid arthritis, though the evidence regarding osteoarthritis is inconsistent. Further, most of this evidence stems from high-income countries. Household air pollution exposure may be an important risk factor for arthritis in low- and middle-income countries (LMICs) but is largely unstudied. Women in these regions can be exposed to high levels of air pollution through cooking activities. Women, in general, are also at higher risk of arthritis, compared to men. We examined household air pollution (electricity vs. gas/kerosene/paraffin; coal/charcoal/wood; or agriculture/crop/animal dung/shrubs/grass used for cooking) as a risk factor for arthritis in 6 LMICs (China, Ghana, India, Mexico, the Russian Federation and South Africa) using data from Wave I of the multiwave panel World Health Organization Study on Global AGEing and Adult Health (SAGE) (2007-2010). The use of liquid (aOR=1.73, 95%CI: 1.33-2.25) or solid (coal/charcoal/wood: AOR=1.73, 95%CI: 1.32-2.27; agriculture/crop/animal dung/shrubs/grass: AOR=2.00 (1.47-2.72) for cooking was strongly associated with an increased odds of arthritis, compared to electricity, in pooled weighted analyses. Sex (female), age ( $\geq 50$  years), obesity (BMI  $\geq 30.00$ ) and the comorbidities angina pectoris, diabetes, chronic lung disease, depression and hypertension were also associated with a higher odds of arthritis. Underweight (BMI  $< 18.50$ ) and higher education levels (college/university completed/post-graduate) were associated with a lower odds of arthritis. This study is among the first to examine household air pollution in LMICs as a risk factor for arthritis. These findings suggest that exposure to household air pollution might be associated with an increased odds of arthritis in these regions.

## **P02.1210. Long-Term Exposure to Ambient PM2.5 and Fasting Blood-Glucose in the Elder Cohort**

Yi Zhang

*Yi Zhang<sup>1</sup>, Tiantian Li<sup>1</sup>, Zaisheng Lin<sup>3</sup>, Xiaoming Shi<sup>2</sup>*

*1. Department of Environmental Health Risk Assessment, National Institute of Environmental Health, Chinese Center for Disease Control and Prevention, Beijing, Beijing, China.*

*2. National Institute of Environmental and Health, Chinese Center for Disease Control and Prevention, Beijing, China.*

*3. Fujian center for disease control and prevention, Fuzhou, China.*

**Abstract:** Background/Aim: Diabetes is one of the major diseases affecting the human health and bringing the heavy disease burden. There are only a few studies which have reported the effects of long-term PM2.5 exposure on the fasting blood-glucose among the elders. Most of them are cross-sectional studies, and the results are inconsistent. Therefore, we have conducted a longitudinal study to determine the association between long-term exposure to ambient PM2.5 and fasting blood-glucose in the elder cohort. Methods: We have followed up 609 subjects older than 60 years subjects in the six counties in China in 2008-2009, 2012 and 2014 in three times. The subjects that accepted fasting blood-glucose test more than once have been included (589 remained in the analysis). The ambient annual ground-level PM2.5 concentration with 0.01°spatial resolution from 2005-2014 was obtained from Atmospheric Composition Analysis Group, Dalhousie University, Canada. The linear mixed effect models were used in the analysis between the PM2.5 and fasting blood-glucose. The main analysis model was adjusted for random subject and county effect, and age, sex, education years, et al. as the fixed effect. Results: The increase of 10µg/m<sup>3</sup> in annual exposure to PM2.5 in the previous year was associated with an increase of the fasting blood-glucose of 0.281 mmol/L (95% confidence interval [CI], 0.169 to 0.393). The subgroup with diabetes had a higher estimated increase of the fasting blood-glucose than the subgroup without diabetes (Z=2.87, P<0.01); the subgroup without exercise regularly had higher estimated increase of the fasting blood-glucose than the subgroup with exercise regularly (Z=2.26, P<0.05). Conclusions: The long-term ambient PM2.5 exposure is associated with the increase of the fasting blood-glucose. The elders with the diabetes are the vulnerable people. And doing exercise regularly is a protective factor.

## **P02.1220. Effects on Morbidity and Mortality of Critical Episodes of PM2.5 in the City of Medellin, 2015**

Juan Piñeros Jiménez

*Emmanuel Nieto Lopez<sup>1</sup>, Hugo Grisales Romero<sup>1</sup>, Nora A. Montealegre<sup>1</sup>, Ana Z. Orrego<sup>2</sup>, Angela L. Molina<sup>2</sup>, Juan G. Piñeros Jiménez<sup>1</sup>*

*2. Area Metropolitana del Valle de Aburrá, Medellín, Colombia.*

**Abstract:** Two critical episodes of PM2.5 were observed in Medellin (level over 75 mg/m<sup>3</sup> for three days or more) on March 15-18 and March 25-28, 2015. The association between acute exposure to PM2.5 during episodes and daily cases of mortality and morbidity and emergency room visits in population under 5 years and adults aged 65 and over was examined in the quarter between February and April 2015. Statistical analyzes of interrupted time series and generalized additive models of Poisson regression were performed. During the episodes, the increase of 10 mg/m<sup>3</sup> in the daily average of PM2.5 was associated with the increase of 4.6% and 6.1% in emergency room visits of children under 5 years of age due to respiratory infection and pneumonia in the same day of the increase, and variations of 6.2% and 4.6% for the cumulative exposure of seven days, respectively. For this age group increases in 3.3% for incident cases of respiratory infection and 5.5% for pneumonia were reported in the same day of exposure and in 6.7% in the distributed delay of 0-7 for both. For all ages and adults 65 and older, the cumulative effects of mortality from respiratory caused increased 2.4% and 4.5%, respectively, per 10 mg/m<sup>3</sup> in the daily average of PM2.5 after 7-day exposure. Compared with the days of the February-April quarter in which the atmospheric episode did not appear on the days of critical episodes, children under 5 years of age presented an excess of 39.4% in emergency room visits due to pneumonia and 22.7% due to respiratory infection. In the same age group, incident cases of pneumonia and respiratory infection increased by 20.9% and 16.15%, respectively, there was also an excess of 13.2% in the asthma crisis. This study report excesses of morbidity and emergency room visits in children under 5 years old during critical episodes in Medellin.

## **P02.1230. Identifying Sensitive Windows for Prenatal Particulate Air Pollution Exposure and Relative Leukocyte Telomere Length in Cord Blood**

Maria Jose Rosa

**Abstract:** Introduction: In utero particulate matter exposure produces oxidative stress that impacts cellular processes that include telomere biology. Newborn telomere length is likely critical to an individual's telomere biology; reduction in this initial telomere setting may result in increased susceptibility to adverse outcomes later in life. We implemented innovative methodology to identify sensitive windows for the associations between prenatal particulate matter with diameter  $\leq 2.5 \mu\text{m}$  (PM<sub>2.5</sub>) and relative leukocyte telomere length (LTL) measured in cord blood. Methods: Women who were residents of Mexico City and affiliated with the Mexican social security system (IMSS) were recruited during pregnancy (n=427 for analyses). Mothers' prenatal exposure to PM<sub>2.5</sub> was estimated based on residence during pregnancy using a satellite-based spatio-temporally resolved prediction model. Cord blood was obtained at the time of delivery and leukocyte DNA was extracted. Duplex quantitative polymerase chain reaction (qPCR) was used to compare the relative amplification of the telomere repeat copy number to single gene (albumin) copy number. A distributed lag model (DLM) incorporating weekly averages was used in order to explore sensitive windows. A sensitive window was identified when the pointwise 95% confidence bands did not contain zero. Results: In models that included child's sex, mother's age at delivery, prenatal environmental tobacco smoke (ETS) exposure, gestational age, birth season and assay batch, we found significant associations between higher PM<sub>2.5</sub> exposure during early pregnancy (4-9 weeks) and shorter LTL in cord blood. A 10  $\mu\text{g}/\text{m}^3$  increase in PM<sub>2.5</sub> during this period resulted in an 8.6% shortening in LTL. Conclusions: Increased PM<sub>2.5</sub> during a specific prenatal window was associated with shorter LTL. Refined determination of time window in which PM has the greatest magnitude of effect can enhance insight into underlying mechanisms.

## **P02.1240. Maternal Exposure to Ambient Ozone and Congenital Diseases in Korea**

Kyung-Shin Lee

*Kyung-Shin Lee<sup>1</sup>, Hyun-Joo Bae<sup>2</sup>, Yun-Chul Hong<sup>3</sup>, Youn-Hee Lim<sup>1</sup>*

*1. Institute of Environmental Medicine, Seoul National University of Medical Research Center, Environmental Health Center, Seoul, Jongno-gu, Korea (the Republic of).*

*2. Korea Environment Institute, Sejong, Korea (the Republic of).*

*3. Department of Preventive Medicine, Seoul National University College of Medicine, Seoul, Jongno-gu, Korea (the Republic of).*

**Abstract:** Previous studies suggested evidence of an effect of exposure to ambient air pollutants on risk of certain congenital heart and structural defects. However, few studies have investigated the effects on endocrine and metabolic diseases. We estimated associations between maternal exposure to ambient ozone (O<sub>3</sub>) and congenital malformations and endocrine and metabolic diseases in Korea. Among infants residing in 251 districts in Korea, cases with 11 congenital anomalies (n=149,325) and controls with non-infective gastroenteritis and colitis (n=1,172,764) at birth were selected from the National Health Insurance Cohort Data during 2008-2013. For each infant, we assigned the various definitions of exposure period based on pregnancy trimesters (1st, 2nd, 3rd, 1st to 2nd, 2nd to 3rd, and 1st to 3rd). Mean of O<sub>3</sub> concentrations prior to the birth was used as a proxy of exposure for the pregnant women based on the residential area. We estimated the effects of O<sub>3</sub> on 11 types of congenital diseases using logistic regression models after controlling for covariates such as sex, income, and year. We observed marginal and significant associations between maternal exposure to O<sub>3</sub> and metabolic diseases and congenital malformations. Maternal O<sub>3</sub> exposure was positively associated with increases in metabolic diseases, 5.4% [95% Confidence Intervals (CI), 0.3%, 10.8%], circulatory system, 9.3% (95% CI, 3.6%, 15.4%), and musculoskeletal system, 5.9% (95% CI, 1.6%, 10.2%). However, there is no significant association between maternal O<sub>3</sub> exposure and the nervous and digestive systems. **Conclusions:** The study contributes to the small body of knowledge regarding the associations between in utero exposure to ozone and congenital and metabolic anomalies, but confirmation of these associations will be needed in future studies. **Funding:** This study was partially supported by grants from the Environmental Health Center funded by the Ministry of Environment, Republic of Korea.

**P02.1250. A Population-Based Study of Traffic-Related and Outdoor Air Pollution during Pregnancy and Autism in Denmark**

Qi Yan

Qi Yan<sup>1</sup>, Beate Ritz<sup>1</sup>, Zeyan Liew<sup>1</sup>, Xin Cui<sup>1</sup>, Matthias Matthias<sup>2</sup>, Jasveer Virk<sup>1</sup>, Ole Raaschou-Nielsen<sup>3</sup>

1. *Epidemiology, UCLA, Los Angeles, CA, United States.*

2. *Aarhus University, Aarhus, Denmark.*

3. *Danish Cancer Society Research Center, Danish Cancer Society, Copenhagen, Cyprus.*

**Abstract:** Background Previous autism spectrum disorder (ASD) and air pollution studies focused on pregnancy exposures, but another vulnerable period is immediate postnatally. Here, we examined early life exposures to air pollution from the pre- to the postnatal period and ASD/ASD subtypes in the Danish population. Methods With Danish registers, we conducted a nationwide case-control study of 15,387 children with ASD born 1989-2013 and 68,139 population controls matched by birth year and sex identified from the birth registry. We generated air dispersion model (AirGIS) estimates for NO<sub>2</sub>, SO<sub>2</sub>, PM<sub>2.5</sub> and PM<sub>10</sub> at mothers' home from 9 months before to 9 months after pregnancy and calculated odds ratios (OR) and 95% confidence intervals (CI), adjusting for parental age, neighborhood socioeconomic indicators, and maternal smoking using conditional logistic regression. Results In models that included all exposure periods, we estimated adjusted ORs for ASD per interquartile range (IQR) increase for 9 month after pregnancy with NO<sub>2</sub> of 1.08 (95% CI: 1.01, 1.15) and with PM<sub>2.5</sub> of 1.06 (95% CI: 1.01, 1.11); associations were smaller for PM<sub>10</sub> (1.04; 95% CI: 1.00, 1.09) and strongest for SO<sub>2</sub> (1.21; 95% CI: 1.13, 1.29). Also, associations for pollutants were stronger in more recent years (2000-2013) and in larger cities compared with provincial towns/rural counties. For particles and NO<sub>2</sub>, associations were only specific to autism and Asperger diagnoses. Conclusion Our data suggest that air pollutant exposure in early infancy but not during pregnancy increases the risk of being diagnosed with autism and Asperger among children born in Denmark.

## **P02.1260. Prenatal and Postnatal Ambient Air Pollution Exposure and Weight Growth Trajectories in Early Childhood**

Anna Rosofsky

*Anna Rosofsky<sup>1</sup>, M. Patricia Fabian<sup>1</sup>, Stephanie Ettinger De Cuba<sup>2</sup>, Megan Sandel<sup>2</sup>, Sharon Coleman<sup>3</sup>, Brent A. Coull<sup>4</sup>, Antonella Zanobetti<sup>4</sup>*

- 3. Biostatistics and Epidemiology Data Analytics Center, Boston University School of Public Health, Boston, MA, United States.*
- 4. Environmental Health, Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

**Abstract:** Background: Air pollution exposure during pregnancy has been positively associated with both low birth weight and higher body mass index later in life. The relationship between perinatal air pollution exposure and weight growth trajectories in early childhood, and the interaction with birth weight has yet to be studied. Methods: We combined electronic medical record (EMR) with survey data collected from caregiver-child dyads enrolled in the ethnically diverse Boston-based Children's HealthWatch cohort (n=4,797). Geocoded residential address at each EMR entry was linked to daily 1 km<sup>2</sup> PM<sub>2.5</sub> predictions. We examined the association between pre- and postnatal (12-month averaging period) PM<sub>2.5</sub> exposure and sex-specific weight (kg) growth trajectories from birth to age six, using piecewise linear and polynomial mixed models. Results: Mean prenatal and postnatal PM<sub>2.5</sub> concentrations were similar between males (prenatal: 9.6 ±1.2 µg/m<sup>3</sup>; postnatal: 7.9 ±0.9 µg/m<sup>3</sup>) and females (prenatal: 9.5 ±1.2 µg/m<sup>3</sup>; postnatal: 7.9 ±1.0 µg/m<sup>3</sup>). Females with prenatal PM<sub>2.5</sub> above the median (9.5 µg/m<sup>3</sup>) had significantly (p<0.05) higher weights versus females with prenatal PM<sub>2.5</sub> below the median from 0-6 years of age (e.g. 0.16 kg higher at 24 months, 0.62 kg higher at 60 months). The association was similar among low birth weight (LBW) (< 2500 g) females (13.3% LBW). Conversely, males with prenatal PM<sub>2.5</sub> above the median had lower weights (e.g. -0.17 kg at 24 months, -0.72 kg at 60 months) than males with prenatal PM<sub>2.5</sub> below the median. Male weight trajectories did not differ by birth weight strata (14.1% LBW). Weight trajectories were not associated with postnatal PM<sub>2.5</sub>. Conclusions: Studying growth trajectories provides an opportunity to understand the life course impact of pre and postnatal air pollution. The findings demonstrate the complex association between environmental exposures and childhood weight gain and that the mechanism of sex-specific effects require additional research.

## **P02.1270. Air Pollution Exposure and Biomarkers of Early Effect in Children: The Final Results of the MAPEC\_LIFE Project**

Umberto Gelatti

*Elisabetta Ceretti<sup>1</sup>, Donatella Feretti<sup>1</sup>, Massimo Moretti<sup>2</sup>, Marco Verani<sup>3</sup>, Francesco Bagordo<sup>4</sup>, Cristina Pignata<sup>5</sup>, Milena Villarini<sup>2</sup>, Annalaura Carducci<sup>3</sup>, Tiziana Grassi<sup>4</sup>, Silvia Bonetta<sup>5</sup>, Umberto Gelatti<sup>1</sup>*

- 5. Department of Public Health and Pediatrics, University of Torino, Torino, Italy.*

**Abstract:** Children are at high risk of suffering health consequences of air pollution and childhood exposure can increase the risk of developing chronic diseases in adulthood. The MAPEC\_LIFE project, funded by EU Life+ Programme (LIFE12 ENV/IT/000614), aimed to evaluate the association between air pollution exposure and biomarkers of early effect in children, and to propose guidance for implementing environmental policies. The study was carried out on 6-8-year-old children living in 5 Italian towns in two different seasons. DNA strand breakage and micronucleus (MN) frequency were investigated in buccal cells of children. Socio-demographic and lifestyle features were investigated using a questionnaire. Air pollution exposure was assessed analysing PM0.5 for chemical composition, toxicity and genotoxicity and collecting data on air quality during the study period. 1149 children were included. Levels of main pollutants were higher in the Northern Italy and in winter. PM0.5 extracts showed slight cytotoxic and mutagenic effects. In winter, the 52.7% of children showed at least one MN in cells (0.44 MN/1000 cells), with significant differences among the towns. In spring, MN frequency was lower than in winter (0.22 MN/1000 cells) and the difference between towns disappears. MN frequency resulted associated with benzene, PM2.5, ozone, SO2 and polycyclic aromatic hydrocarbons. Environmental tobacco smoke, BMI and diet showed to influence MN frequency, as well. DNA strand breakage was higher in spring (179.02 au) than in winter (159.00 au) with significant differences among the towns (only in winter). DNA damage was associated with benzene, PM2.5, SO2, NO2 and ozone. Socio-demographic and lifestyle features did not influence the damage. In conclusion, the assessment of biomarkers of early effect in the population is useful in evaluating the impact of air pollution exposure. Results obtained can be used to propose some guidance for implementing policies for public health protection.

**P02.1280. Oxidative Potential and Metals in Ambient Particulate Matter are Associated with Inflammatory and Neural Biomarkers in a Controlled Exposure Study**

**Abstract:** Background: Oxidative stress/inflammation is an important pathway leading to particulate matter-associated disease status. We studied the effects of metals and oxidative potential (OP) in urban particles on biomarkers of systemic inflammation, oxidative stress and neural function. Methods: Fifty-five healthy non-smoking volunteers, mean age 28 years, were exposed to coarse (2.5-10  $\mu\text{m}$ , mean 213  $\mu\text{g}/\text{m}^3$ ), fine (0.15-2.5  $\mu\text{m}$ , 238  $\mu\text{g}/\text{m}^3$ ), and/or ultrafine concentrated ambient particles (<0.3  $\mu\text{m}$ , 136  $\mu\text{g}/\text{m}^3$ ). Exposures lasted 130 minutes, separated by  $\geq 2$  weeks. OP (ascorbate or glutathione depletion in synthetic lung fluid) and metals in particles were measured. Blood and urine samples were collected pre-exposure, and 1-hr and 21-hr post exposure to determine biomarkers. We used mixed-regression models to assess associations between exposures and changes in biomarker levels adjusting for age, sex, BMI, season, particle size and mass. Results: Results were expressed as percent change from daily pre-exposure biomarker levels per mean pollutant concentration. Exposure to OP was significantly associated with increased blood inflammatory and neural biomarkers. E.g. C-reactive protein increased 146% (95% CI 44%-248%), neural biomarker ubiquitin C-terminal hydrolase L1 (UCHL1) increased 9.4% (1.8%-17.1%), and urinary lipid oxidation marker malondialdehyde (MDA) increased 19.4% (3.6%-35.3%) 21 hours post exposure. Exposure to various metals (Al, Cu, K, Ni, Sn, Ti and/or V) were significantly associated with increased blood interleukin-6 and blood and urinary VEGF, blood neural markers UCHL1, and urinary vanillylmandelic acid, homovanillic acid and cortisol, and urinary DNA oxidation marker 8-hydroxy-deoxy-guanosine and blood MDA. OP and metals were moderately correlated. Conclusion: OP and metals in ambient particles may influence biomarker levels that reflect systemic inflammation, oxidative stress, perturbations of blood-brain barrier integrity and physiological stress.

## **P02.1290. A Structural Approach to Analyzing Urban Population Dust Exposure and Its Effect on Daily Morbidity**

Abstract: Urban population is often challenged by high dust exposure and suffered with various health effects. Daily morbidity due to exposure is difficult to analyze since exposure time, human susceptibility and surviving effects varies. We propose an alternative approach for reducing bias linked with time-varying confounding variables. Urban population groups in Rawalpindi city including students, traffic police wardens, bus-drivers and students were analyzed. We aimed to assess dust exposure effects owing to job nature and time spend on road on daily morbidity, using time-series model ARIMA (Autoregressive Integrated Moving Average), to adjust time-varying confounding factors. We also apply a logistic regression model and compare both b-estimation outcomes with standard principal component generated scores for morbidity. Job titles were analyzed for exposure hazards using b-estimation in urban cohorts (n=358) on total and respiratory infection morbidity. Findings derived from ARIMA revealed daily dust exposure (7:00 to 9:00am) and job nature as strong predictors for upper respiratory tract infections. The Risk Ratio obtained from logistic model to total mortality compared with overall morbidity of urban population for the duration of follow up to the risk had nobody been exposed was 2.33 (CI: 1.03-4.26), and asthma risk ratio morbidity was 1.69 (CI: 1.16-3.97). Scores derived from principal component analysis for physical symptoms (sneezing, cough, eye redness, and eye irritation) were similar to hazard ratio approximations that lead to frequent hospital emergency room visits per month. Our study conclude that effect estimate for daily morbidity is highest for bus-drivers as they spend more time on road followed by traffic warden and students. The differential effect among study cohorts may partially show exposure time as prime determinant of health effects and hence interventions in the form of reduced job hours and use of masks are suggested to reduce exposure.

**P02.1300. Associations between High Air Pollutant Levels and Cardiovascular Diseases in Taipei, Taiwan**

**Abstract:** The association between air pollution and the occurrence of cardiovascular diseases has been demonstrated in many epidemiological studies. Extreme air pollution levels such as those resulted from meteorological events might affect the human health differently than the lower ones. However, in most studies, the effects of these extreme conditions were not evaluated separately. Therefore, we conducted a study to explore the association between high levels of air pollutants and cardiovascular diseases in Taipei City in Taiwan. We retrieved data on the outpatient visits between January 1, 2006 and December 31, 2010 from the National Health Insurance Research Database (NHIRD), which contain all the claims from a random sample of one million people. We obtained data on ambient levels of carbon monoxide (CO), nitrogen dioxide (NO<sub>2</sub>), ozone (O<sub>3</sub>), and particulate matters less than 2.5 microns (PM<sub>2.5</sub>) and 10 microns (PM<sub>10</sub>) in diameter from five air quality monitoring stations in Taipei. A quantile regression model was used to evaluate the associations between the 3-day moving average of population weighted concentrations of the pollutants and the number of outpatient visits for cardiovascular diseases. During the study period, the cohort members paid a total of 191974 outpatient visits for cardiovascular diseases. According to the estimating parameter of least absolute deviations, we found that the quantiles of CO, O<sub>3</sub>, NO, NO<sub>2</sub> and PM<sub>10</sub> did not have stable relationship with visits for cardiovascular diseases, except for PM<sub>2.5</sub>. We observed a positive correlation between the level of PM<sub>2.5</sub> and the number of outpatient visits for cardiovascular diseases. In particular, the estimating parameter was higher than 0.6 when the 3-days moving average of PM<sub>2.5</sub> level was higher than 44.29 µg/m<sup>3</sup> (i.e. the 90th quantile). Therefore, the government should consider alarming patients with cardiovascular diseases when the ambient PM<sub>2.5</sub> is expected to reach a certain level.

**Abstract:** Background/Aim: Diabetes research has recently taken into consideration the potential influence of air pollution on diabetes risk. However, epidemiologic evidence linking air pollution to diabetes remains inconsistent. This study sought to assess the relationship between selected air pollutants (NO<sub>2</sub>, PM<sub>2.5</sub>, O<sub>3</sub>, and Ox [oxidant capacity]) and the incidence of diabetes. Methods: Our cohort consisted of ~4.8M adults aged 35 to 85 who were long-term Ontario residents prior to cohort inception in 2001. The cohort was followed until 2015. Long-term exposure to NO<sub>2</sub>, PM<sub>2.5</sub>, and O<sub>3</sub> was estimated using satellite-based remote sensing, land-use regression model, and fusion-based approach, respectively, and was assigned to subjects' annual postal code addresses. Ox was calculated as the redox-weighted average of O<sub>3</sub> and NO<sub>2</sub>. Diabetes incidence was ascertained using population-based health administrative data with a validated algorithm. For each air pollutant, we estimated its association with diabetes using standard Cox proportional hazards models, adjusting for multiple individual-level and area-level covariates (e.g., SES and healthcare accessibility). We performed sensitivity and stratified analyses to assess the robustness of the estimates, and modelled the shape of air pollutant-diabetes associations using Shape Constrained Health Impact Functions. Results: Over the study period, 790,461 cohort members were diagnosed with diabetes. We found that each IQR increase in exposure to NO<sub>2</sub> was associated with a hazard ratio of 1.06 (95% CI: 1.05-1.06). This relationship was relatively robust to sensitivity analyses considered, and exhibited a near-linear shape. There were positive associations between diabetes and PM<sub>2.5</sub> (1.02 per IQR, 95% CI: 1.01-1.02), O<sub>3</sub> (1.002 per IQR, 95% CI: 0.999-1.01), and Ox (1.01 per IQR, 95% CI: 1.01-1.01), but these estimates were sensitive to different models considered. Conclusions: Air pollution, especially NO<sub>2</sub>, was linked to increased diabetes risk.

**P02.1320. Association of the daily ratio of FEV1 to FVC with the real-time exposure level to indoor PM2.5 and CO2 after controlling for other risk factors in adult non-smoking refractory asthmatics in urban areas of South Korea: Results from Environmental Health St**

Sol Yu

**Abstract:** Background As acute exacerbations of refractory asthma (RA) can be fatal, it is important to recognize the risk factors with consideration that the immune system may undergo continuing change by age among adults and adult asthmatics tend to stay indoor. We evaluated the associations between variation in daily exposure levels to indoor air quality, and daily changes in lung function (FEV1/FVC ratio) of RA sufferers, after controlling for total immunoglobulin E (IgE) levels, smoking status, and seasonality. Methods We analyzed sensing technology based spirometry data from refractory asthmatics whose mean FEV1/FVC ratio is lower than < 80%, lived in Seoul or Kyunggi Province, South Korea , and attended hospital between 2016 and 2017 with multiple exacerbations. We constructed mixed model using the data clustered within each patient. Results We analysed 1100 episodes data relating to 25 never-smoking patients. After adjusting for sex, age, body mass index (BMI), and total IgE level, a unit increase in concentration of particles  $\leq 2.5 \mu\text{m}$  (PM2.5), or CO2 concentration on Lag 0, reduced the FEV1/FVC ratio by 0.1% (95% confidence interval [CI]: 0.0–0.4%). Patients living in house with high damp scores (3 and 4) showed lower ratio than the others (1 and 2). Conclusions This study demonstrated that reduction in pulmonary function in adult asthma patients were potentially associated with acute exposure to increased indoor PM2.5, CO2 and damp levels with irrespective to total IgE level.

**P02.1330. Air Pollution Exposures and Risk of High Blood Pressure in Diabetes Mellitus Patients, China: A Retrospective Cohort Study**

**Abstract:** Background: Air pollution exposures have been associated with hypertension, but limited studies have examined the associations in diabetes mellitus patients. Objectives: We aimed to examine the associations of exposure to air pollution with risk of hypertension in diabetes mellitus patients. Methods: We identified hypertension cases from hospital records among patients who were previously diagnosed as diabetes mellitus from January 2013 to May 2017. We used generalized additional models to estimate adverse effects of air pollution on systolic/diastolic blood pressure in diabetes patients. Results: A total of 2,050 patients were enrolled in this study. A 10 $\mu\text{g}/\text{m}^3$  increase in PM<sub>2.5</sub>, PM<sub>10</sub>, SO<sub>2</sub>, and O<sub>3</sub> exposure was associated with an increased risk of higher systolic blood pressure [D1] level (risk ratio (RR) =1.001; 95% confidence interval (CI):1.000, 1.002; RR =1.001; 95%CI: 1.000, 1.002; RR =1.004; 95%CI: 1.001, 1.006). Significant associations were observed with fasting blood glucose (fbg)  $\geq 7.0$  mmol/L, overweight/ obesity, and younger age. Little evidence has been observed for the associations between particulate matter (PM), SO<sub>2</sub> and O<sub>3</sub> exposure and diastolic blood pressure in present study. Conclusions: In our study, diabetes patients were at increased risk for higher blood pressure when exposed to higher residential PM and SO<sub>2</sub>. Individuals with higher BMI, younger age, and FBG  $\geq 7.0$  mmol/L were more susceptible to ambient air pollution.

**P02.1331. Size-Fractionated Particle Number, Length, and Surface Area Concentrations and Daily Mortality in Augsburg, Germany, 2004-2009**

Kai Chen

*Kai Chen<sup>1</sup>, Susanne Breitner<sup>1</sup>, Jianwei Gu<sup>1</sup>, Regina Ruckerl<sup>1</sup>, Kathrin Wolf<sup>1</sup>, Annette Peters<sup>1</sup>, Josef Cyrys<sup>1</sup>, Alexandra E. Schneider<sup>1</sup>*

**Abstract:** Background: Although epidemiological studies have shown positive associations between ultrafine particles (UFP) and daily mortality, evidence on different particle metrics and size fractions is lacking. Objectives: We explored the associations of daily mortality with short-term exposure to size-fractionated particles measured in number, length, and surface area concentrations in Augsburg, Germany. Methods: We collected daily data on total natural mortality, size-fractionated particle number concentration (PNC), length concentration (PLC), and surface area concentration (PSC) (10-1000 nm) during November 2004 to December 2009. We further collected daily PM<sub>2.5</sub>, PM<sub>10</sub>, NO<sub>2</sub>, and O<sub>3</sub>. We estimated associations between particles and mortality using Poisson generalized additive models with over-dispersion, while accounting for ambient temperature, long-term and seasonal trend, day of the week, influenza epidemics, and population dynamics due to summer vacation and holiday. Results: We found positive and delayed (lag 6) associations between particles 10-500 nm and daily mortality in all three metrics. For example, an interquartile range increase in PNC<sub>10-30</sub>, PNC<sub>30-50</sub>, PNC<sub>50-100</sub>, and PNC<sub>100-500</sub> was associated with 2.53% (95% CI: 0.04, 5.09%), 1.91% (95% CI: -0.14, 4.01%), 1.88% (95% CI: -0.17, 3.97%), and 1.86% (95% CI: -0.19, 3.96%) increase in total natural mortality. The corresponding estimates for UFP (10-100 nm) and PNC<sub>10-500</sub> were 2.16% (95% CI: 0.02, 4.00) and 2.26% (0.06, 4.50), respectively. Using PLC or PSC metrics yielded weaker and nonsignificant estimates. No associations with natural mortality were found for particles 500-1000 nm. Associations between size-fractionated PNC, PLC, and PSC remained similar after adjustment for mass concentrations of PM and gaseous pollutants. Conclusions: Size-fractionated PNC within 10-500 nm were associated with natural mortality in Augsburg, whereas no associations were observed for particles within 500-1000 nm (mainly secondary aerosol).

**P02.1340. Implications of Exposure Measurement Error for Interpreting Epidemiological Results for Studies of Exposure to PM, NO<sub>2</sub>, or SO<sub>2</sub>: Effect of Error Type on Bias and Coverage Probability**

Jennifer Richmond-Bryant

*Jennifer Richmond-Bryant<sup>1</sup>, Tom Long<sup>1</sup>*

*1. National Center for Environmental Assessment, Environmental Protection Agency, Research Triangle Park, NC, United States.*

Abstract: In epidemiologic studies of health effects of air pollutant exposure, measurements or models are used to estimate exposure concentration. These estimates have some errors that propagate to health effect estimates in exposure-response models. We critically evaluate effect of exposure error type on bias and coverage probability (CP) to understand conditions affecting interpretation of exposure-response models. We evaluate differences in bias and CP from exposure error for epidemiologic studies of exposure to PM<sub>2.5</sub>, NO<sub>2</sub>, and SO<sub>2</sub>. We review available literature on exposure error for short-term and long-term exposure studies. For short-term exposure studies, temporal confounding (temporal factors such as season influence both exposure and health outcome) decreases CP and increases positive bias, implying the true health effect is larger than predicted and model uncertainty grows with increasing bias. Population error (single daily exposure concentration does not account for variation in exposure due to time-activity during a day) and nonambient (indoor) sources bias the health effect estimate towards the null and decreases CP, so uncertainty grows with increasing bias while underestimating the true health effect. Spatial error (deviation between true exposure concentration at an individual's location and concentration at a receptor) was relatively unbiased but in some instances resulted in lower CP. For long-term exposure studies, spatial confounding (spatial factors such as residential location influence both exposure and health outcome) produced positive bias with lower magnitude than for short-term exposure studies. Most spatial errors did not bias the health effect estimate. In both cases, large uncertainties were observed when exposure concentration was modeled with low spatial and temporal resolution for a spatially-variable pollutant. Views expressed in this abstract are of the authors and do not necessarily reflect views or policies of the U.S. EPA.

**P02.1350. Maternal Exposure to Ozone and PM2.5 and the Prevalence of Orofacial Clefts in Four U.S. States**

Ying Zhou

Ying Zhou<sup>1</sup>

1. CDC, Atlanta, GA, United States.

**Abstract:** Background: While there is some evidence that maternal exposure to ambient air pollution is associated with orofacial clefts in offspring, the epidemiologic studies have been largely equivocal. We evaluated whether maternal exposure to elevated county-level ambient fine particulate matter with aerodynamic diameter  $\leq 2.5 \mu\text{m}$  (PM2.5) and ozone during early gestation was associated with a higher prevalence of orofacial clefts. Methods: Birth data consisting of 4.7 million births from 2001-2007 were obtained from National Birth Defects Prevention Network for four states - Arizona, Florida, New York (excluding New York City), and Texas. The air pollution exposure assessment for gestational weeks 5-10 was based on county-level average concentrations of PM2.5 and ozone data generated using a Bayesian fusion model available through CDC's Environmental Public Health Tracking Network. Two outcomes were analyzed separately: cleft lip with or without cleft palate, cleft palate alone. In logistic regression analyses, we adjusted for factors that were suspected confounders or modifiers of the association between the prevalence of orofacial clefts and air pollution, i.e., infant sex, race-ethnicity, maternal education, smoking status during pregnancy, whether this was mother's first baby, maternal age. Results: Each  $10 \mu\text{g}/\text{m}^3$  increase in PM2.5 concentration was significantly associated with cleft palate alone (OR = 1.43, 95% CI: 1.11-1.86). There was no significant association between PM2.5 concentration and cleft lip with or without cleft palate. No associations were observed between ozone exposure and the two outcomes of orofacial clefts. Conclusions: Our study suggests that PM2.5 significantly increased the risk of cleft palate alone, but did not change the incidence of cleft lip with or without palate. Ozone levels did not correlate with incidence of orofacial clefts.

## **P02.1360. Longitudinal Analysis of Particulate Air Pollutants and Executive Function in Southern California Youth**

Diana Younan

**Abstract:** Executive function (EF) is critical for social well-being and mental/physical health. Previous studies on ambient air pollution and EF have produced mixed results, and the suggested adverse effect was largely inferred from studies only measuring sub-domains of EF in school-age children with limited follow-up. We conducted a prospective study to examine whether residential ambient air pollution affects EF from late childhood to early adulthood in urban-dwelling populations. A multi-ethnic cohort of Southern California twins/triplets (N=829) was examined in 2000-2014 (aged 9-21 years), each with repeated EF assessments of Preservative Responses (cognitive flexibility) and Nonperseverative Errors (control of attention resources and self-monitoring) from the Wisconsin Card Sorting Test (WCST), an integrated testing battery for frontal lobe damage. We estimated ozone and PM<sub>2.5</sub> using generalized additive models, NO<sub>x</sub>/NO<sub>2</sub> using land use regression models, freeway and non-freeway NO<sub>x</sub>/NO<sub>2</sub> using CALINE4 dispersion models, and elemental carbon using the UCD/CIT chemical transport model. Monthly exposure time-series were aggregated to derive 1-, 2-, and 3-year averages preceding each EF assessment. Multilevel mixed-effects models were used to estimate the exposure effects on continuous standard scores of EF. Long-term PM<sub>2.5</sub> (range of IQRs: 4.86-5.25 µg/m<sup>3</sup>) was significantly (all p<0.05) associated with poorer performance in both WCST measures, with effect sizes equivalent to 4.5-7 years of delay in EF development, adjusting for potential confounders (sociodemographics; neighborhood quality and socioeconomic characteristics; other pollutants; spatial covariates; maternal and early-life risk factors). No consistent associations were found with other exposure measures. These results provide strong evidence that long-term PM<sub>2.5</sub> exposure contributes to reduced EF, suggesting that the frontal lobe may represent a brain region most vulnerable to air pollution neurotoxicity.

## **P02.1380. Evaluate the Validity of Land Use Regression Models for NO<sub>2</sub> Based on Routine and Campaign Monitoring Data from an Urban Area of Japan**

Saori Kashima

*Saori Kashima<sup>1</sup>, Takashi Yorifuji<sup>2</sup>, Norie Sawada<sup>3</sup>, Tomoki Nakaya<sup>4</sup>, Akira Eboshida<sup>1</sup>*

*1. Department of public health and health policy, Institute of Biomedical and Health Sciences, Hiroshima University, Hiroshima, Japan.*

*2. Department of Human Ecology, Graduate School of Environmental and Life Science, Okayama University, Okayama, Japan.*

*3. Epidemiology and Prevention Group, Center for Public Health Sciences, National Cancer Center, Tokyo, Japan.*

*4. Graduate School of Environmental Studies, Tohoku University, Sendai, Japan.*

**Abstract:** Background: Generally, land use regression (LUR) models have been built using campaign monitoring data rather than routine monitoring data. However, the routine monitoring data have advantages such as low cost and long-term coverage. The objective of this study was to compare the predictability of LUR models for NO<sub>2</sub> based on routine and campaign monitoring data obtained from an urban area. This evaluation considered that LUR models that could represent regional differences in air pollution exposure and regional road structure were optimal. Method: We selected the city of Suita in Osaka (Japan). We built a model based on routine monitoring data obtained from all sites (routine-LUR), and a model based on campaign monitoring data (campaign-LUR) within the city. The routine LUR models were based on monitoring networks across two prefectures (i.e., Osaka and Hyogo prefectures). Next, we selected 30 evaluation sites and developed LUR models excluding these evaluation sites. We calculated the predictability of each model, and compared the predicted NO<sub>2</sub> concentrations from each model with measured annual average NO<sub>2</sub> concentrations from evaluation sites. Results: The predictability for NO<sub>2</sub> concentrations of routine-LUR model was better than that of campaign-LUR model: Adjusted R<sup>2</sup> = 0.68 and 0.59, respectively, and root mean square error = 3.4 ppb and 3.9 ppb, respectively. The routine-LUR model were highly correlated with the measured NO<sub>2</sub> concentrations at evaluation sites [ $\rho = 0.88$ ] comparing with the campaign-LUR model [ $\rho = 0.54$ ]. Although the predicted NO<sub>2</sub> concentrations from each model were correlated, the LUR models based on routine networks provided better visual representations of the local road conditions in the city. Conclusion: The present study demonstrated that LUR models based on routine data could estimate local traffic-related air pollution in an urban area. The importance and usefulness of data from routine monitoring networks should be acknowledged.

## **P02.1390. Social Susceptibility to Multiple Air Pollutants in Cardiovascular Disease**

Jamie Humphrey

*4. Geography, University of Colorado Boulder, Boulder, CO, United States.*

Abstract: Cardiovascular disease (CVD), the leading cause of death in the U.S., has been linked to chronic and acute air pollution exposures. Research has identified stronger effects of air pollution in lower-socioeconomic position (SEP) communities, where exposures are also often higher. While specific factors leading to this susceptibility remain unknown, chronic psychosocial stress related to social adversity has been hypothesized as a critical component. In this study, we aim to examine associations between air pollution exposures and CVD events using a case-crossover design, and assess effect modification of these associations by community SEP and/ or specific chronic stressor exposures (e.g., crime, deprivation). We quantify relationships between exposures and CVD events in NYC using four unique datasets: [1] Spatial data on citywide community SEP and stressor indicators; [2] Surfaces for fine-scale spatial variation in multiple pollutants from NYC Community Air Survey [fine particles (PM<sub>2.5</sub>), nitrogen dioxide (NO<sub>2</sub>), summertime ozone (O<sub>3</sub>), sulfur dioxide (SO<sub>2</sub>)]; [3] Daily ambient pollution concentrations from EPA AQS monitors; [4] Complete data on in- and out-patient unscheduled CVD events presented in NYC emergency departments (ED) 2005-2011 (n = 1.3 million), from NY State Department of Health Statewide Planning and Research Cooperative System. In preliminary analyses, we observed 1.0 to 3.5% increases in excess risk of CVD ED visits - for both overall CVD risk and key sub-diagnoses (e.g., acute myocardial infarction, stroke) with a 10-ppb increase in ozone exposure on lag days 0-1. Associations with CVD for ozone on lag days 2-6 days were not significant. We have found suggestive evidence of effect modification by SEP and stressors including violent crime; we found the lowest excess risk of a CVD event in communities in the lowest-crime quartile (e.g., 0.9% excess risk on lag day 0), and increasing risks with increasing crime (e.g., 3.1% excess risk on lag day 1).

## **P02.1400. Air Pollution and Childhood Autism Spectrum Disorder in Taiwan**

How-Ran Guo

*1. Department of Environmental and Occupational Health, National Cheng Kung University, Tainan, Taiwan.*

*2. Language Education Center and Department of Tourism, Food and Beverage Management, Chang Jung Christian University, Tainan, Taiwan.*

**Abstract:** Air pollutants have been linked to some diseases in human, including those of the respiratory and cardiovascular systems. However, their effects on the nervous system were less frequently evaluated. Autism Spectrum Disorders (ASD) is a group of neurodevelopmental disorders of which the etiology is still unknown. We conducted a study in Taiwan to evaluate the possible associations between exposure to air pollutants and ASD. From the one million people in the Taiwan National Insurance Research Database, which is a random sample of the general population, we identified all the infants born between 1996 and 2000. We followed them till the end of 2013 and identified cases of ASD. We traced back the mother's residence and assess the exposure to air pollutants using the data obtained from the air quality monitoring database maintained by the government, which included ozone (O<sub>3</sub>), carbon monoxide (CO), nitrogen dioxide (NO<sub>2</sub>), sulfur dioxide (SO<sub>2</sub>), and particles with diameter less than 10 μm (PM<sub>10</sub>). The effects of the exposures in five different periods were evaluated, including the three trimesters, the whole gestation, and the month right after birth. Cox proportional hazard models were constructed to evaluate the associations between pollutants and childhood ASD. We indentified a total of 29,282 newborns. After adjusting for other risk factors, an increase of 10 ppb of NO<sub>2</sub> was associated with a hazard ratio (HR) of 1.19 (95% confidence interval [CI]: 1.03-1.37) for developing ASD in the first trimester and an HR of 1.15 (95%CI: 1.01-1.33) in the second trimester. A 1 μg/m<sup>3</sup> increase in PM<sub>10</sub> was associated with an adjusted HR of 0.99 (95%CI: 0.98-0.99) in the month of birth and an adjusted HR of 0.99 (95%CI: 0.98-0.99) in the third trimester. In conclusion, we found that exposure to NO<sub>2</sub> in the first two trimesters was associated with an increased risk of developing childhood ASD, but exposure to PM<sub>10</sub> was not.

## **P02.1410. Ambient Air Pollution and the Risk of Stroke and Atrial Fibrillation: A Population-Based Cohort Study**

**Abstract:** Background: Atrial fibrillation (AF) is the leading arrhythmia and a major risk factor for stroke. There is growing evidence linking air pollution to stroke incidence, but less is known for AF. We assessed the association between air pollution, first-ever hospitalization for stroke, and newly diagnosed cases of AF. We also sought to characterize the shape of air pollutant-disease relationships. Methods: We assembled a population-based cohort of 5,071,956 long-term Ontario residents, who were aged 35-85 years and free of stroke and AF on 1 January 2001. Incidence of stroke and AF were ascertained using validated algorithms and health administrative databases. For subjects' residential postal codes, we estimated 5-year mean concentrations of fine particulate matter (PM<sub>2.5</sub>), nitrogen dioxide (NO<sub>2</sub>), and ozone (O<sub>3</sub>) from satellite-derived data, land-use regression models, and fusion-based methods, respectively, and the redox-weighted average of NO<sub>2</sub> and O<sub>3</sub> (Ox). Using Cox proportional hazards models, we estimated the associations between air pollutants, stroke, and AF, adjusting for individual- and neighborhood-level characteristics. We used newly developed non-linear risk models to characterize the shape of pollutant-disease relationships. Results: During the 14-year follow-up, we found 122,545 incident strokes and 313,157 incident AF cases. Each interquartile range increment of PM<sub>2.5</sub>, NO<sub>2</sub>, O<sub>3</sub>, and Ox was associated with increased risk of stroke [HRs (95% CIs) of 1.05 (1.03-1.07), 1.04 (1.01-1.06), 1.05 (1.03-1.06), and 1.05 (1.04-1.06), respectively]. Air pollution exposure was associated with 1% to 3% increased risk of AF. Associations remained after additional adjustments (e.g., comorbidities and spatial random effects Cox models). In pollutant-disease relationships, stroke was found to be near linear for PM<sub>2.5</sub> and sublinear for Ox. For AF, the shapes were both sublinear for PM<sub>2.5</sub> and Ox. Conclusions: Air pollution exposure was associated with stroke and AF onset.

## **P02.1420. Comparison of Different Hybrid Modeling Methods for the Estimation of Intraurban Air Pollutant Concentrations**

**Abstract:** Exposure to air pollution - a major potential environmental factor - can exert significant health effects on the urban population. The improvement of modeling methods to estimate the concentrations of air pollutants within a complex city should be important for exposure assessment of subjects in health studies. This paper presents several hybrid modeling approaches to simulate highly resolved variability in ambient air pollution in the capital of South Korea, Seoul. They combine the Community Multiscale Quality (CMAQ), a regional photochemical model with fine scale models including the California Puff (CALPUFF) dispersion model and the land use regression (LUR) model. We compared the high-resolution spatial pollutant concentration estimates from four different hybrid combinations: 1) raw CMAQ-CALPUFF; 2) observation-fused CMAQ-CALPUFF; 3) raw CMAQ-LUR; 4) observation-fused CMAQ-LUR. We quantitatively evaluated the simulated concentrations with field data from mobile measurements carried out during the winter season. The results showed that significant differences in sub-grid variability of pollutant concentrations were found according to different hybrid modeling methods and observation-fused hybrid modeling can generally improve the model performance in a complex urban area. Our study suggests that a properly evaluated hybrid modeling approach could increase the accuracy of air pollutant concentration estimates for the purpose of improving exposure assessment in a health study.

## **P02.1440. Land Use Regression Modelling: An Air Pollution Monitor Location Optimization Approach**

Matthew Adams

*Matthew Adams<sup>1</sup>*

*1. Geography, University of Toronto Mississauga, Mississauga, ON, Canada.*

Abstract: Land use regression (LUR) modelling associates measured pollution levels to land cover characteristics for spatial interpolation. LUR is commonly applied in the domain of air pollution and less commonly for noise, soil and water pollution. Model outputs can be applied to estimate human or environmental exposure. The model's predictor variables include land use attributes, such as land cover and transportation network characteristics that are calculated within spatial buffers of the monitoring locations. LUR models can be used to predict values at unobserved locations. The application of spatial interpolation attempts to ensure that data are not extrapolated beyond the bounds of the observed values. However, our research identifies that without guaranteeing monitoring data be collected in all land use classes and conditions, it is possible with LUR to actually be extrapolating data and still be within the 2-dimensional spatial boundaries of the monitoring locations. This potential extrapolation occurs because the interpolation is based on a multi-dimensional space that sits upon the 2-D plane, which creates a new set of boundaries for the interpolation. In this paper, we define and demonstrate the potential problem of ensuring LUR models interpolate within both the 2-D spatial domain and the multi-dimensional space that is applied in LUR modelling. We then demonstrate a solution to this problem in a simulated dataset and in an empirical dataset. First, we identify all possible monitoring locations. Second, the objective function is defined with the goal of selecting monitoring locations to maximize the variation across land use conditions. A heuristic search technique is applied to identify good potential solutions. The location of monitors is identified using an ensemble of potential optimum solutions.

## **P02.1450. All-Cause Mortality Risks Associated with Long-Term Exposure to Ambient Fine Particulate Matter in the Chinese Healthy Longevity Cohort**

Tiantian Li

*Tiantian Li<sup>1</sup>, Yi Zhang<sup>1</sup>, Jiaonan Wang<sup>1</sup>, Dandan Xu<sup>1</sup>, Patrick Kinney<sup>2</sup>, Xiaoming Shi<sup>1</sup>*

*2. Boston University, Boston, MA, United States.*

**Abstract:** There is extensive evidence from cohort studies in North America and Europe for increased mortality risk from long-term exposure to fine particulate matter (PM<sub>2.5</sub>). However, this association has rarely been quantified at higher ambient concentrations. We sought to estimate the hazard ratio (HR) for all-cause mortality from long-term exposures to PM<sub>2.5</sub> exposure in a well-defined Chinese cohort of older adults. The Chinese Longitudinal Healthy Longevity Survey (CLHLS) study is a prospective cohort study of elderly men and women enrolled in 2008 and followed through 2014 for mortality events. We studied 13,344 subjects for whom residential locations during the follow-up period were available for linkage to 1 km gridded PM<sub>2.5</sub> concentrations, derived from ground-based measurements and satellite remote sensing. The outcome measure was all-cause mortality. Cox proportional hazards models were used to estimate the effect of long-term PM<sub>2.5</sub> concentrations on all-cause mortality, controlling for age, sex, smoking status, drinking status, physical activity, BMI, household income, marital status, education. We then applied our results to estimate PM<sub>2.5</sub>-related premature mortality for persons older than 65 years-of-age in all of China in 2010. The overall HR for a 10 mg/m<sup>3</sup> increase in 3-year average PM<sub>2.5</sub> concentration was 1.08 (95% CI: 1.06-1.09). There was strong evidence for differences in effects by urban/rural, north/south and high/low PM<sub>2.5</sub> exposure. The HR was higher in rural and southern regions, and at lower PM<sub>2.5</sub> exposure levels. The estimated total PM<sub>2.5</sub> related all-cause mortality of Chinese elderly was 1,765,820 in 2010. Long-term exposure to PM<sub>2.5</sub> was associated with an increased risk of all-cause mortality among elderly adults in China, but the magnitude of the risk declined as concentrations increased.

## **P02.1460. Estimating Concentrations of PM2.5 Species with Random Forest Algorithm across Continental United States during 2005 - 2015**

Jiaozhao Bi

*Xia Meng<sup>1</sup>, Jianzhao Bi<sup>1</sup>, Yang Liu<sup>1</sup>*

*1. Emory University, Atlanta, GA, United States.*

Abstract: PM2.5 is a complex mixture of chemical species, which are emitted from various emission sources; however, currently, PM2.5 is regulated and its health effects are mainly studied based on total mass concentrations. Identifying the differential toxicity of PM2.5 species should be able to provide scientific evidence for more effectively regulatory control of PM2.5 pollution. We develop national models based on random forest algorithm by incorporating land use parameters, meteorological variables and GEOS-Chem simulated concentrations of PM2.5 species to predict ground-levels of PM2.5 sulfate, nitrate, OC and EC across Continental United States from 2005 to 2015. Overall, the random forest models achieve high validation R2 values based on daily predictions, which are 0.80 - 0.90 for sulfate and nitrate, and 0.70 - 0.80 for OC and EC during the study period. With the help of importance rankings of random forest algorithm, our modeling method is able to figure out unique combinations of potential significant contributors among large number of predictors for predicting different PM2.5 species. The long-term temporal trends of predictions of PM2.5 sulfate, nitrate, OC and EC match well with their corresponding ground measurements. The prediction maps capture both regional patterns and hotspots of the four PM2.5 species. Therefore, our national models could provide exposure assessment with high spatial and temporal flexibility for epidemiological studies to better understand the acute and chronic toxicity of PM2.5 speciation across locations in Continental United States.

## **P02.1470. Spatiotemporal Modeling of Oxidative Potential of Ambient Particulate Matter Using Chemical Transport Model-Derived Emission Sources**

Abstract: Multiple epidemiologic studies have found associations between the oxidative potential (OP) of fine particulate matter (PM<sub>2.5</sub>) and adverse cardiorespiratory outcomes, supporting the hypothesis that PM may be capable of inducing oxidative stress. However, limited observational data on OP restrict the scope of exposure and epidemiologic analyses. Here, an advanced PM<sub>2.5</sub> emission source impact analysis is used with limited OP observations to develop and apply a model capable of simulating daily OP over a wide spatial domain, specifically across the eastern United States. OP of ambient water-soluble PM<sub>2.5</sub> was measured using an acellular dithiothreitol (DTT) assay at four locations across the southeastern United States from June 2012-July 2013. PM<sub>2.5</sub> source apportionment was performed during the same time period across the eastern United States using CMAQ-DDM with advanced data assimilation techniques to minimize biases. These sources were related to ambient OP measurements using multivariate linear regression with backward selection. The resulting model was applied to estimate spatio-temporal trends in ambient OP across the eastern United States. Regression analyses show that vehicles and fires significantly contribute to OP, supporting previous findings. Higher OP is generally seen in the winter than the summer and in urban areas compared to rural areas. The intraurban spatial distribution driven by vehicle impacts was briefly investigated, showing a high spatial correlation with RLINE modeled primary roadway concentrations. The CMAQ-DDM modeling approach may be useful for health studies utilizing exposure data across a large study domain (e.g. multiple cities), can integrate a broad range of OP measurements, and can help to identify sources of PM with high OP for regulatory purposes. While this work was supported in part by a grant from the US EPA, this abstract does not necessarily reflect EPA policy.

## **P02.1490. The Contribution of Residential Coal Combustion to the Oxidative Potential of Atmospheric Fine Particulate Matter in Beijing, China**

Abstract: Human exposure to atmospheric fine particulate matter (PM<sub>2.5</sub>) is associated with various health effects such as respiratory and cardiovascular diseases. The adverse effects of inhaled PM<sub>2.5</sub> has been demonstrated to have a strong link with cellular oxidative stress through generation of reactive oxygen species (ROS). Recent studies show that residential coal combustion has significant contribution to ambient PM<sub>2.5</sub> in winter in the Northern China due to its low temperature and incomplete combustion conditions. Moreover, coal combustion is the major source of metals and quinones in the atmosphere in Beijing, which could induce the formation of ROS. To address the oxidative potential of PM<sub>2.5</sub> from residential coal combustion and its contribution to ambient PM<sub>2.5</sub> in Beijing, PM<sub>2.5</sub> samples were collected from residential coal combustion from source tests in the laboratory and at an ambient urban site in Beijing during fall and winter, 2014. Organic carbon (OC), elemental carbon (EC), soluble ions and trace metals were analyzed. The amount of hydroxyl radical (OH) generated by collected PM, which is the most reactive ROS species, was also measured in an aqueous buffered extract solution as a surrogate lung fluid (SLF). Our preliminary results showed that OH production per unit PM mass (ng/Kg PM) from chunk coal was lower than that from honeycomb coal. However, the total OH production by PM from burning one Kg honeycomb coal (ng/Kg coal) was much higher than that from chunk coal, due to higher emission factor of PM from honeycomb coal. The results of receptor-based source apportionment showed that coal combustion and vehicle exhaust were the major sources contributing to PM oxidative potential in fall and winter in Beijing. As PM<sub>2.5</sub> concentration increased, the contributions of coal combustion and industry source also increased.

## **P02.1500. Low Vitamin D Levels Are Associated with Elevated Cardiovascular Responses after a Controlled Diesel Exhaust Exposure in Healthy Human Subjects**

Jaime Mirowsky

- 4. US EPA, Chapel Hill, NC, United States.*

Abstract: Cardiovascular disease accounts for over 17 million deaths per year. There is a large body of evidence suggesting that vitamin D deficiency is associated with cardiovascular disease and disease risk factors. In addition, researchers have found that exposures to ambient air pollution - particularly particulate matter (PM) - represent an added and independent risk factor for cardiovascular morbidity and mortality. Therefore, we wanted to assess whether vitamin D levels are associated with a heightened adverse cardiovascular response to diesel exhaust in healthy human subjects. Using a randomized, crossover study design, 13 healthy, young adults were exposed on two separate occasions to 300 µg/m<sup>3</sup> diesel exhaust and filtered air under controlled conditions. Before, after, and 18 hrs following each exposure, blood samples were collected. The average vitamin D concentration before clean air exposures was 22.3 ng/mL, and the average vitamin D concentration before diesel exposures was 23.4 ng/mL (paired t-test; p = 0.44). Four participants were considered vitamin D deficient (vitamin D < 20 ng/mL), 7 participants had inadequate vitamin D levels (vitamin D between 21-29 ng/mL), and 2 were vitamin D sufficient (vitamin D > 30 ng/mL). Positive and significant associations were observed between baseline vitamin D concentrations and tPA ( $\beta = 6.93$ , 95% CI = -0.30, 13.57), while a negative and significant association was found with plasminogen ( $\beta = -2.84$ , 95% CI = -5.07, 0.61). At 0 hrs post exposure, there were significant negative associations between baseline vitamin D concentrations and D-dimer ( $\beta = 0.02$ , 95% CI = -0.04, 0.00) and IL-8 ( $\beta = -0.03$ , 95% CI = -0.06, 0.00). Additionally, at 18 hrs post exposure negative associations were found between baseline vitamin D concentrations and PAI-1 ( $\beta = -0.03$ , 95% CI = -0.07, 0.01) and TNF- $\alpha$  ( $\beta = -0.03$ , 95% CI = -0.06, 0.00). This suggests vitamin D deficiency might be associated with elevated cardiovascular responses.

## **P02.1510. Household Energy and Health in India: A Situational Assessment and Stakeholder Mapping**

Bhargav Krishna

*Bhargav Krishna<sup>1</sup>, Vidushi Bahuguna<sup>2</sup>, Samayita Ghosh<sup>2</sup>, Banalata Sen<sup>3</sup>*

- 1. Centre for Environmental Health, Public Health Foundation of India, New Delhi, India.*
- 2. Centre for Chronic Disease Control, New Delhi, India.*
- 3. Independent Researcher, New Delhi, India.*

**Abstract:** Background: Air pollution is a major and growing risk factor, contributing significantly to India's burden of disease. While there is a growing recognition that access to clean household energy for lighting, heating and cooking is pivotal for improving health, socio-economic conditions and environmental protection, over 60% of rural Indians are caught in the 'chulha trap', reliant on solid fuels like wood or dung for cooking and heating. Several initiatives have been undertaken across various government departments over the years to address household air pollution ranging from provision of cleaner chulhas to LPG connections. Methods: In this study, we undertook a stakeholder mapping exercise to understand the landscape of household energy and health interventions in India. In doing so, we document historical and current policies related to household air pollution (HAP) and its health impacts undertaken by the central and two state governments (Rajasthan and Maharashtra). We also collected secondary data on interventions and held discussions with stakeholders from the government, private sector and civil society to understand perceptions around health impacts of HAP, role of environmental health in policy development and decision-making, and factors associated with implementation of programmes on household energy and health. Conclusions: Through this study, we identify the challenges in implementation and the importance of introducing behaviour change and awareness campaigns of health impacts of HAP, without which existing interventions may not succeed. We also recognize the need to reform governance structures by enabling inter-ministerial dialogue and coordination, strengthening regulatory mechanisms, monitoring and evaluation of interventions as a means of continuous learning and placing health centrally in decision-making related to household energy and health in India.

## **P02.1511. Review of the Acute Effects of the Daily Exposure to Particulate Matter on Lung Function and Lung Inflammation in Healthy Subjects**

Alan da Silveira Fleck

*Alan da Silveira Fleck<sup>1</sup>, Margaux Sadoine<sup>1</sup>, Maximilien Debia<sup>1</sup>, Audrey Smargiassi<sup>1</sup>*

*1. Department of Environmental and Occupational Health, Université de Montreal Public Health Research Institute, School of Public Health, Université de Montreal, Montreal, QC, Canada.*

**Abstract:** The effects of daily exposure of particles in ambient air on acute respiratory outcomes have shown inconsistent results, and no meta-analysis about this topic has been performed. We aimed to review studies on the association between the daily exposure to particles in ambient air and in occupational settings, and their acute effects on lung function and lung inflammation of healthy adults. Original studies published between 2000 and 2017 were searched in Web of Science, Medline and Pubmed. Studies were included if they assessed exposure to particles (number or mass concentration), and measured at least one spirometric parameter or fractional exhaled nitric oxide (FeNO). Studies were excluded if respiratory outcomes were not measured within 24 hours after exposure, if there was no baseline for health outcomes or if the study population was not composed of healthy adults. 2447 studies were considered, and 239 studies were retained after the first screening (title + abstract). The final selection included 51 environmental (27 cross-over, 20 panel and 4 cross-sectional studies) and 34 occupational studies (27 cross-shift, 5 cross-over and 2 panel studies). The most frequent fractions of particulate matter assessed were PM<sub>2.5</sub> (41), PM<sub>10</sub> (20) and UFP (19). 31 studies evaluated FeNO, while 70 studies included spirometric measures (FEV<sub>1</sub> (63), FVC (48), PEF (32) and FEV<sub>1</sub>/FVC (20) were the most frequent). Population (i.e. age) and exposure characteristics (i.e. duration, composition, type of monitoring, exposure levels) varied greatly between studies. There was also a large variability in the associations observed. Future studies should assess factors that explain such variability.

## **P02.1520. Integrating Spatiotemporal Variability and Modifiable Factors into Air Pollution Estimates**

Naomi Zimmerman

*Naomi Zimmerman<sup>2</sup>, Hugh Z. Li<sup>1</sup>, Aja Ellis<sup>1</sup>, Aliaksei Hauryliuk<sup>1</sup>, Ellis S. Robinson<sup>1</sup>, Peishi Gu<sup>1</sup>, Luke Snell<sup>3</sup>, R Subramanian<sup>1</sup>, Allen L. Robinson<sup>1</sup>, Joshua S. Apte<sup>3</sup>, Albert Presto<sup>1</sup>*

- 2. Mechanical Engineering, The University of British Columbia, Vancouver, BC, Canada.*
- 3. The University of Texas at Austin, Austin, TX, United States.*

**Abstract:** City-wide air pollution measurements have typically relied on a small number of widely separated regulatory monitoring sites or land use regression (LUR) maps built using time-integrated samples to assess population-scale exposure. However, air pollutant concentrations may exhibit significant spatial and temporal variability depending on local sources and features of the built environment, which are poorly captured by the existing monitoring regime. To better understand urban spatiotemporal pollution gradients on the <1 km scale, 15 fixed air quality monitoring stations were deployed in Pittsburgh, PA from August 2016-May 2017; this was complemented with mobile sampling in ~1 km<sup>2</sup> grids around the fixed stations. The fixed stations were deployed at locations with a range of traffic, restaurant and population densities. The fixed stations included measurements of ultrafine particle number (UFP), PM<sub>2.5</sub>, and a low-cost air quality monitor, the Real-time Affordable Multi-Pollutant (RAMP) sensor package for measuring CO, NO<sub>2</sub>, O<sub>3</sub>, and CO<sub>2</sub>. Pollutant time series from the fixed stations were deconvolved using wavelet decomposition to separate short-lived (<2h) pollution events from partial-day events (2-8h) and persistent enhancements (baseline changes >8h) above the regional background. The combined short-lived (<2h) and persistent enhancement pollutant signals are hypothesized to represent the 'local' pollutant characteristics of a site. Compared to the total pollutant signal, the average local and persistent enhancement pollutant signals were better correlated with modifiable factors typically used as covariates in land-use regression building. The findings support building more accurate and time-resolved LURs, which may be more transferable to other domains by isolating the truly 'local' pollutant signal. These improved LURs will enable better air pollutant exposure estimates and aid in the identification of environmental policy priorities towards improved air quality.

## **P02.1530. Ambient Particulate Matter and Cardiovascular Incidence in a Nationwide Cohort in South Korea**

Sun-Young Kim

*Ok-Jin Kim<sup>1</sup>, Sun-Young Kim<sup>1</sup>*

*1. Graduate School of Cancer Science and Policy, National Cancer Center, Goyang-Si, Korea (the Republic of).*

**Abstract:** While ambient particulate matter (PM) was suggested as a risk factor for cardiovascular disease (CVD) in North American and European cohort studies, some studies in other countries reported weak or negative associations. We aimed to investigate the association between chronic exposure to PM with a diameter less than 10  $\mu\text{m}$  (PM<sub>10</sub>) and incident CVD and to identify susceptible population using a national cohort in South Korea. Our study population included 142,028 adults in the National Health Insurance Service-National Sample Cohort who were more than 30 years old, underwent health examination, and had not diagnosed with CVD for 2002-2006. The incident CVD was defined as the first hospital visit for 2007-2013, based on the International Classification Diseases, 10th revision. The chronic PM<sub>10</sub> exposure for each person was computed as the 5-year average for 2002-2006 using residential district-level annual mean concentrations predicted by a previously-developed exposure prediction approach. Cox proportional hazard models were applied for estimating hazard ratios (HR) and 95% confidence intervals (CI) of incident CVD per 10  $\mu\text{g}/\text{m}^3$  increase in PM<sub>10</sub> after adjusting for individual- and area-level risk factors. In addition, we examined the effect medication by sex, age groups (<65 or others), income (<20%), type of health insurance (employee insured), smoking (current, past, or never smoker), obesity, and disease status of hypertension, hyperlipidemia, and diabetes. The 59,791 people had a first diagnosis during 262,031,184 person-year. We did not find the association between PM<sub>10</sub> and incident CVD for all population [HR=0.99 (95% CI=0.98, 1.01)]. In the subgroup analysis, there was a significant difference by age groups with a positive association in the elderly [1.06 (1.00, 1.12)]. This study, as the first nationwide cohort study of air pollution and morbidity in South Korea, provides an evidence of higher risk of incident CVD for chronic exposure to PM<sub>10</sub> in elderly people.

**P02.1550. Fine Particulate Matter and Medications Dispensed during and after a Brown Coal Mine Fire: A Time Series Analysis**

Yuming Guo

*Amanda Johnson<sup>1</sup>, Joanna Dipnall<sup>1</sup>, Martine Dennekamp<sup>1</sup>, Grant Williamson<sup>2</sup>, Caroline Gao<sup>1</sup>, Matthew Carroll<sup>1</sup>, Christina Dimitriadis<sup>1</sup>, Jillian Ikin<sup>1</sup>, Fay Johnston<sup>2</sup>, Alexander McFarlane<sup>3</sup>, Malcolm Sim<sup>1</sup>, Dion Stub<sup>1</sup>, Michael J Abramson<sup>1</sup>, Yuming Guo<sup>1</sup>*

*1. Monash University, Melbourne, VIC, Australia.*

*2. University of Tasmania, Hobart, TAS, Australia. 3. University of Adelaide, Adelaide, SA, Australia.*

**Abstract:** Background: Very few studies have examined the impacts of coal mine fire smoke on human health. The aim of this study was to assess the association between prolonged mine fire smoke PM<sub>2.5</sub> exposure from a coal mine fire that burned over a six week period in 2014 and medications dispensed across five localities in South-eastern Victoria, Australia. Maximum hourly mine fire-related PM<sub>2.5</sub> concentrations were estimated to reach 3700 µg/m<sup>3</sup>. Methods: Spatially resolved PM<sub>2.5</sub> concentrations were retrospectively modelled using The Air Pollution Model, a dispersion model coupled with a chemical transport model (TAPM-CTM). Data on medications dispensed were collected from the Pharmaceutical Benefits Schedule database for 2013-2016. Poisson distributed lag time series analysis was used to examine associations between daily mine fire-related PM<sub>2.5</sub> concentrations and daily counts of medications dispensed for respiratory, cardiovascular and mental health conditions. Confounding variables included: seasonality, long-term trend, day of the week, maximum ambient temperature and public holidays. Results: Positive associations were found between mine fire-related PM<sub>2.5</sub> and increased risks of medications dispensed for respiratory, cardiovascular and mental health conditions, after lag 2-5 days. A 10 µg/m<sup>3</sup> increase in coal mine fire-related PM<sub>2.5</sub> was associated with a 15% (95%CI 8-23%) increase in respiratory medications dispensed, a 12% (9-16%) increase in cardiovascular medications dispensed and a 17% (12-22%) increase in mental health medications dispensed. Conclusions: Mine fire PM<sub>2.5</sub> exposure was associated with increased medications dispensed for respiratory, cardiovascular and mental health. These findings can help to develop the public health response in the event of future mine fires.

## **P02.1580. A Study on the Key Role of Cadmium Accumulation Induced by PM2.5 Exposure in Renal Injury**

Xingya Kuang

*Xingya Kuang<sup>1</sup>*

*1. Yangpu Hospital, Tongji University, Shanghai, China.*

Abstract: PM2.5 has attracted more and more attention to the damage of the kidney. PM2.5 and heavy metal cadmium both have been proved to play an important role in renal injury. However, the role of heavy metal cadmium in renal injury induced by PM2.5 exposure have not been reported. This research chose serious heavy metal pollution in industrial area and relatively clean living area, starting from the comparison of different regional differences in the cadmium content in PM2.5, through cell experiments in vitro and population studies. The results showed that the survival rate of renal tubular epithelial cells (HK2) was significantly decreased by 100  $\mu\text{g} / \text{ml}$  of PM2.5 extract in the living area, while the survival rate of renal tubular epithelial cells was significantly decreased at 50  $\mu\text{g} / \text{ml}$  of PM2.5 in industrial area. The results showed that the nephrotoxicity of PM2.5 in industrial area was greater than that in living area. The concentration of PM2.5 and total dust in industrial polluted area and clean living area were analyzed simultaneously. It was found that the concentration of PM2.5 in industrial polluted area was significantly higher than that in living area control group. The contents of some heavy metals (manganese, mercury, cadmium) were significantly higher than those in the control group. The contents of heavy metals in blood or urine of 168 residents (excluding occupational exposure to heavy metals and nephropathy) were measured. It was found that the concentration of urinary cadmium in the observation group was significantly higher than that in the control group, but there was no significant difference in the contents of other heavy metals (blood lead, urine manganese, urine mercury, urinary arsenic) between the two groups. It was found that the concentration of cadmium and metallothionein (MT) was positively correlated with the indexes of renal injury, which reflected the key role of cadmium accumulation induced by PM2.5 in renal injury.

## **P02.1590. Exposure to Ambient Ultrafine Particles and Nitrogen Dioxide and Incident Acute Myocardial Infarction and Congestive Heart Failure: A Population-Based Cohort Study**

**Abstract:** Background. Although long-term exposure to traffic-related air pollutants such as nitrogen dioxide (NO<sub>2</sub>) has been linked to cardiovascular mortality and morbidity, little is known about the effect of ultrafine particles ( $\leq 0.1\mu\text{m}$  in diameter; UFPs) on the incidence of major cardiovascular events. We conducted a population-based cohort study to assess the associations of chronic exposure to UFPs and NO<sub>2</sub> with the incidence of acute myocardial infarction (AMI) and congestive heart failure (CHF). Methods. We used the Ontario Population Health and Environment Cohort (ONPHEC) to assemble our study cohorts which comprised all long-term Ontario residents who were aged 30 to 100 years and free of respective study outcomes, and lived in the City of Toronto, Canada on January 1st, 1996. Subjects were followed until December 31st, 2012. Outcomes were ascertained using validated province-wide databases. We estimated annual concentrations of UFPs and NO<sub>2</sub> using land-use regression models and assigned these estimates to participants' annual postal-code addresses during the follow-up period. Using random-effects Cox proportional hazards models, we calculated hazard ratios (HRs) and 95% confidence intervals (CIs) for UFPs and NO<sub>2</sub>, adjusted for individual- and neighborhood-level covariates. We considered both single- and multi-pollutant models. Results. Between 1996 and 2012, we identified 106,644 and 43,745 incident cases of AMI and CHF, respectively. Each interquartile change in exposure to UFPs ( $\sim 10,000$  count/cm<sup>3</sup>) was associated with increased risk of incident AMI (HR=1.05; 1.02-1.07) and CHF (HR=1.03; 1.02-1.05) after adjusting for all covariates. These results remained unaltered with further control for fine particulate matter (PM<sub>2.5</sub>) and NO<sub>2</sub>. Exposure to NO<sub>2</sub> was also independently associated with higher incidence of CHF. Conclusion. Exposure to traffic-related air pollution including UFPs and NO<sub>2</sub> may increase the risk of incident cardiovascular events.

**P02.1600. What Explains LPG Adoption? Role of Culture, Women's Empowerment, and Economics, Using the Indian Human Development Survey, 2005 and 2012**

**Abstract:** INTRODUCTION According to the Global Burden of Disease study, household air pollution from cooking with solid fuels killed over 700,000 Indians in 2016. Major national initiatives aim to combat the problem via increased distribution of connections to subsidized Liquefied Petroleum Gas (LPG). Here, we examine the relationship between LPG adoption / disadoption and household factors. METHODS We used the 2005 and 2012 Indian Human Development Survey (IHDS), a nationally representative multi-topic panel dataset (re-contact rate: 84%). Using linear regressions, we estimated associations between LPG adoption/disadoption and (1) household economic status (income, assets, and consumption) and (2) cultural factors, including women's empowerment. We developed a gender / women's empowerment score based on questions on independence, family dynamics and decision making, and a binary variable for whether men eat first in the family. RESULTS Of the 12926 households (HH) who owned LPG in 2005, 1181 (9%) gave up LPG in 2012. Of the 23226 HH who did not have LPG in 2005, 5400 (23%) acquired LPG in 2012. We found significant association of economic and cultural factors with (1) LPG ownership in 2005, (2) LPG ownership in 2012, and (3) adoption/disadoption between 2005 and 2012. For example, for HH without LPG in 2005, holding all other variables constant, the odds of the HH acquiring LPG is 32% lower for HH where men eat first than in other HH ( $p < 0.001$ ). For HH with LPG in 2005, holding all other variables constant, odds of the HH disadopting LPG is 39% higher for HH where men eat first than in other HH ( $p < 0.001$ ). CONCLUSION Women empowerment can explain some of the dynamics of adoption and disadoption of clean-cooking options, and are potentially as important or more important than economic factors.

## **P02.1610. Impact of Global Change in Sulfur Dioxide, Black Carbon and Organic Carbon on PM2.5-Related Premature Mortality and Years Life Lost**

Abstract: Previous research has highlighted the importance of major atmospheric aerosols such as sulfate, through its precursor sulfur dioxide (SO<sub>2</sub>), black carbon (BC) and organic carbon (OC), and their effect on global climate regimes, specifically on their impact on particulate matter of size less than or equal to 2.5 micrometers in diameter (PM<sub>2.5</sub>). Coupled with these global climate simulations, are studies which highlight the negative effects of PM<sub>2.5</sub> on human health. Globally, national policies attempt to address the change of these major active aerosols and their impact on PM<sub>2.5</sub>, which would later on presumably have a cascading effect towards the change of health risks. This study aims to determine how the change in the global anthropogenic aerosol emissions affect health, in particular through the change in attributable mortality (AN) and years of life lost (YLL). Model for Interdisciplinary Research on Climate (MIROC), a global atmospheric general circulation model (AGCM) developed by several Japanese institutions, was used to estimate the gridded atmospheric aerosol (SO<sub>2</sub>, BC, and OC) data for 0.25 by 0.25 degrees. The gridded data were then utilized to estimate the associated cause-specific risks via an integrated exposure response function, and its consequent disease burden, in terms of AN and YLL, per WHO Regions. SEARO and WPRO regions were observed to have apparent variations in AN and YLL with respect to the change in atmospheric aerosols. If atmospheric aerosols were to be reduced, both SEARO and WPRO will have co-benefits (reduced AN) among the cerebrovascular population. On the other hand, if life expectancy were to be considered, co-benefits (reduced YLL) were apparent among acute lower respiratory infection population, for both regions. The changes in the atmospheric aerosols have varying impact on the changes in the disease burden landscape globally, which could translate to varying health-oriented aerosol mitigation policies.

**P02.1620. A Difference in Difference Approach to Estimating the Effect of PM2.5 on Mortality Rates in the Northeastern and Mid-Atlantic U.S.**

**Abstract:** Background: Dozens of cohort studies have associated PM2.5 exposure with early deaths. However, few studies have used causal modeling techniques, particularly methods robust to omitted confounders. We assessed the effect of annual PM2.5 exposure on all-cause mortality rates among the Medicare population in the Northeastern and MidAtlantic states, using the difference-in-differences approach for causal modeling. Methods We obtained records of Medicare beneficiaries aged 65 years or more who reside in the Northeastern or MidAtlantic states from 2000 to 2013 and followed each participant from the year of enrollment to year of death or 2013. We estimated the causal effect of annual PM2.5 exposure on mortality rates using the difference-in-differences approach in a Poisson survival analysis. We controlled for individual confounders, for spatial differences in confounders using dummy variable for each ZIP code and for state-wide time trend as a surrogate for temporal confounders using a penalized spline of year. Results We included 112,376,805 person years from 15,401,064 people, of whom 37.4% died during the study period. The inter-quartile range (IQR) of the annual PM2.5 concentration was 3 µg/m<sup>3</sup>, the mean annual PM2.5 concentration ranged between 6.5 µg/m<sup>3</sup> and 14.5 µg/m<sup>3</sup> and over 75% were below 12 µg/m<sup>3</sup>. An IQR incremental increase in PM2.5 was associated with a 4.04% increase (95% CI 3.49%; 4.59%) in mortality rates. Conclusions Assuming no predictors changing differentially across ZIP codes over time in parallel with similar changes in PM2.5, we found a causal effect of PM2.5 on mortality incidence rate in a population with low exposure.

## **P02.1630. Metabolic and Pulmonary Health Effects of Ozone and Black Carbon Exposure in Young Adult Runners**

Vivian C. Pun

*Vivian C. Pun<sup>1</sup>*

*1. National University of Singapore, Singapore, Singapore.*

Abstract: Physical activity has been shown to promote health and well-being, however, exercising in environments with high level of air pollution can increase the risk of health problems ranging from reduced exercise capacity, high blood pressure to cardio-respiratory impairments. In this crossover study, we investigated the impact of short-term exposure to black carbon (BC) and ozone on metabolic and pulmonary functions among thirty healthy young adult runners after 30-minutes run on a clean and polluted route on separate days in August 2015 in Hong Kong. Measurements of systolic and diastolic blood pressures, forced vital capacity, forced expiratory volume in 1 second, peak expiratory flow and fractional exhaled nitric oxide were collected pre- and post-run. Real-time ambient concentration of BC was measured at the route, whereas concentration of ozone was obtained from Hong Kong Environmental Protection Department air monitoring station nearest to the running routes. Our runners were on average 20 years old, with mean body mass index of 20.3 kg/m<sup>3</sup>. Air pollution concentrations were higher in the polluted route than in the clean route, with the highest difference in BC (5,397 ng/m<sup>3</sup> versus 1,340 ng/m<sup>3</sup>). In single-pollutant regression models, no significant association was found between air pollution and changes in metabolic or pulmonary biomarkers adjusting for gender, type of route, temperature and relative humidity. However, when adjusting for both BC and ozone simultaneously, an interquartile range increment in BC became statistically significantly associated with increase in systolic blood pressure (17.82; 95% CI: 2.56, 33.09) after running exercise. No significant association was found for ozone upon adjusting for BC. Our finding of BC is consistent with existing literature, while further studies with greater sample size and longer exposure time are needed to investigate the effects of ozone to metabolic/lung functions in runners.

## **P02.1640. Use of Spatial Models to Predict Ambient O<sub>3</sub> and NO<sub>x</sub> Concentrations in Tianjin, China**

**Abstract:** Nitrogen oxides (NO<sub>x</sub>) and ozone (O<sub>3</sub>) are important ambient air pollutants that have been associated with a variety of adverse health effects. In North America and Europe, land-use regression (LUR) models have been widely developed to estimate pollution concentrations at a high spatial resolution. Although these models included traffic fleet composition and/or traffic counts/density as important predictors, such information is usually unavailable in developing countries. In China, LUR has only recently been applied in limited areas. We aimed to characterize NO<sub>x</sub> and O<sub>3</sub> concentrations and develop LUR models to predict their spatial distributions using solely publicly-available data in Tianjin, a major coastal city in China that is heavily polluted by traffic and industrial emissions. Seasonal NO<sub>x</sub> and O<sub>3</sub> samples were collected at 49 locations across Tianjin. Heavy-duty vehicle counts estimated from 0.5 m x 0.5 m satellite images correlated well with field-measured counts collected at a different time, thus supporting the use of high-resolution satellite images to assess vehicle traffic. We found that concentrations of NO<sub>x</sub> were highest in winter, while the opposite pattern was observed for O<sub>3</sub>. The majority of the variance in NO<sub>x</sub> concentrations was explained by heavy vehicle traffic, tree cover, and season. For O<sub>3</sub>, the variance was mostly explained by distance to airports, distance to roads, and distance to coal plants. Measured vs. predicted NO<sub>x</sub> concentrations following model calibration showed good predictive ability for NO<sub>x</sub> (R<sup>2</sup>=0.64 with field-measured heavy-duty vehicle count; R<sup>2</sup>=0.59 with satellite-based heavy-duty vehicle count) and O<sub>3</sub> (R<sup>2</sup>=0.70) models. This study provides utility for researchers investigating air pollution in regions where field-measured vehicle traffic data are not available, as well as for policy makers and public health officials seeking to understand the sources and spatial distribution of air pollution in Tianjin.

**P02.1650. Effects of Air Pollution While Being Physically Active, the Potential for Modification: A Review of the Literature**

*2. Centers for Disease Control and Prevention, Atlanta, GA, United States.*

Abstract: Air pollution is known to be associated with morbidity and mortality, while physical activity is consistently encouraged due to its health benefits. It is well established that exercise increases the dose of environmental pollutants that enter the lungs. However, it is not clear if the risk of this increased dose outweighs the benefits of exercise. There is a lack of consensus regarding recommendations for exercising outdoors when air pollution is high. To help understand this complex issue, we reviewed the peer-reviewed literature related to exposure to air pollution modified by physical activity separated into two areas of interest: (1) the acute impacts of air pollution while exercising, and (2) the impacts of air pollution among those who routinely engage in physical activity. This review focuses on the first area. Articles were identified through PubMed, Science Direct, ProQuest Agricultural & Environmental Science Database searches on terms encompassing air pollution and exercise/physical activity (n=334). After screening, 30 papers were included and largely occurred in North America (n=15) and Europe (n=12), while the remaining papers (n=3) occurred in either Asia, Africa, or Australia. Papers were included in the review if they contained (1) exercising in clean air, (2) exercising in polluted air, (3) rest in clean air, and (4) rest in polluted air. The ongoing review of these papers has yielded mixed results. We have identified four studies that conclude that physical activity decreases the detrimental impact of air pollution, similarly two studies found air pollution negates the beneficial effects of physical activity. However, six studies found physical activity and air pollution did not interact, while eight studies found physical activity only increases exposure to air pollutants. The remaining studies (n=10) have not met the criteria for our review. This abstract does not necessarily reflect EPA policy.

## **P02.1660. Intra-Urban Exposure to PM2.5 in Mexico City Associated with Acute Cardiovascular and Cerebrovascular Mortality from 2004-2013**

Iván Gutiérrez-Avila

**Abstract:** Background. Limited evidence exists about short-term exposure to different intra-urban concentration levels and composition of particulate matter with aerodynamic diameter  $\leq 2.5\mu\text{m}$  (PM2.5) associated with acute cardiovascular and cerebrovascular mortality. Methods. We used an ecologic approach and Generalized Linear Mixed Models (GLMM) with Poisson regressions in order to assess daily exposure to PM2.5 associated with all cardiovascular, all cerebrovascular and ischemic heart mortality in people  $\geq 25$  and  $\geq 65$  years for each one of the sixteen boroughs of Mexico City for the period from 2004-2013. Exposure to PM2.5 was evaluated with estimates from a new hybrid spatiotemporal model using satellite measurements of Aerosol Optical Depth (AOD-PM2.5) with resolution of 1 km<sup>2</sup> from NASA for same day exposure (lag0), and average of the current and previous day (lag0-1). The high spatial resolution of this model also allowed for the daily borough-level PM2.5 mean estimates to be weighted to account for population density. Spatial heterogeneity was tested by comparing the significance of the inclusion of the random-intercepts and random-slopes terms versus only the inclusion of the random-intercept term in our GLMM. Results. Exposure to AOD-PM2.5 varied from 21.6  $\mu\text{g}/\text{m}^3$  to 26.9  $\mu\text{g}/\text{m}^3$ . A 10- $\mu\text{g}/\text{m}^3$  increase in AOD-PM2.5 was associated with all cardiovascular mortality [0.2% (95%CI:0.11-0.29) to 2.3% (95%CI:2.19-2.39), increase], all cerebrovascular mortality [0.4%(95%CI:0.05-0.69) to 2.1% (95%CI:1.79-2.49), increase] and ischemic heart disease [0.6% (95%CI:0.6-0.68) to 3.8% (95%CI:3.77-3.91)] for lag0. Cerebrovascular mortality in people  $\geq 65$  showed the strongest associations for lag0 and lag0-1. Cardiovascular mortality in people  $\geq 25$  years was the only mortality outcome showing significant spatial heterogeneity. Conclusion. Intra-urban variation in PM2.5 concentration was associated with acute cardiovascular and cerebrovascular mortality within Mexico City.

**P02.1670. The Association of Long-Term Air Pollution Exposure with Blood Pressure, Vascular Stiffness and Prevalent Hypertension: Results from Compass Cohort Participants.**

Saira Tasmin

*Saira Tasmin*<sup>1</sup>

*1. Department of Public Health Sciences, University of Chicago, Chicago, IL, United States.*

Abstract: Long-term air pollution exposure has been reported to be associated with cardiovascular mortality and morbidity in many studies, but little is known about hypertension, vascular stiffness and blood pressure. The aim of this study is to examine the cross-sectional relationship of long-term air pollution exposure with hypertension, blood pressure and vascular stiffness in Chicago. Multiethnic Prevention And Surveillance Study (COMPASS), a cohort study investigating how lifestyle, healthcare, environment, and genetics affect health. This analysis included 3119 participants 27-94 years of age who were enrolled in Chicago from 2013-2016. Systolic and diastolic blood pressure (SBP and DBP, respectively), pulse pressure (PP), and vascular stiffness measured as brachial artery distension (BAD) were collected using the DynaPulse 2000A. The long-term exposures to particles with an aerodynamic diameter < 2.5 $\mu$ m (PM<sub>2.5</sub>) and nitrogen dioxides (NO<sub>2</sub>) for the 3-year periods prior to enrollment were estimated at residential addresses from validated spatio-temporal models. We conducted a cross-sectional analysis of associations between air pollution and SBP, DBP, PP and BAD with linear regression, and prevalent hypertension with logistic regression, adjusting for potential demographic and socioeconomic covariates. Effect modification by obesity and ethnicity will be investigated by stratified analysis. We found evidence that the increased PM<sub>2.5</sub> exposure was associated with higher SBP, PP and BAD, but not with DBP. The results were inconsistent for NO<sub>2</sub>. We are still analyzing the data and results of final models with estimated values will be reported in the conference.

**P02.1680. Effects of Air Pollution on Acute and Chronic Kidney Disease: Using the National Health Insurance Service - National Sample Cohort (NHIS-NSC) Data in Korea**

Clara Kim

*Clara T. Kim<sup>1</sup>, Ho Kim<sup>2</sup>*

*1. HALLYM UNIVERSITY, Chuncheon, Korea (the Republic of).*

*2. Seoul National University, Seoul, Korea (the Republic of).*

**Abstract:** In order to prevent and manage the environmental and health hazards caused by air pollution, the preparation of the scientific evidenced data is very important. However, the health impact assessment of kidney diseases caused by air pollution is very limited. Kidney disease is a disease that is likely to have co-existing with cardiovascular disease, and air pollution has a great effect on vascular disease, so it is expected that it will adversely affect kidney disease. In this study, we investigated the relationship between air pollutants and kidney disease exacerbations in Seoul using national sample cohort data from National Health Insurance Service in Korea. The data includes about 1 million subjects and the period is from 2002 to 2013. It includes medical examination details, medical history, prescription history, and personal information for all members of the health insurance scheme and the beneficiaries. The analyzed areas were Seoul, and persons including N17 and N18 of the Korean Standardized Disease Code in the main disease / injuries on the medical service statement were selected as the study subjects. Because of the nature of the illness, we excluded all cases such as reserved medical care. Therefore, this study limited the subjects to emergency hospitalization to confirm the short - term effect of air pollution on kidney disease. Air pollution data are on the following five substances: carbon monoxide (CO), ozone (O<sub>3</sub>), fine dust (PM<sub>10</sub>), nitrogen dioxide (NO<sub>2</sub>), idealized sulfur (SO<sub>2</sub>). We used case-crossover analysis. The control day was selected for the same day of the month (28) as the case day for exposure to air pollution. Acute kidney disease was affected by air pollution but relatively chronic kidney disease was less affected by air pollution. Especially, in case of acute renal disease, the risk of emergency hospitalization increased with increasing SO<sub>2</sub>, and the delayed effect showed that the risk increased with lag.

## **P02.1690. Effect of Traffic-Related Air Pollution on Spontaneous Baroreceptor Sensitivity: A Trial of In-Vehicle Filtration**

Michael Young

*Michael Young<sup>1</sup>, Karen Jansen<sup>1</sup>, Tim Gould<sup>1</sup>, Coralynn Sack<sup>1</sup>, Laura Hooper<sup>1</sup>, James Stewart<sup>1</sup>, Tim Larson<sup>1</sup>, Sverre Vedal<sup>1</sup>, Joel D. Kaufman<sup>1</sup>*

*1. University of Washington, Seattle, WA, United States.*

Abstract: Human controlled exposure studies suggest that diesel exhaust causes acute changes in blood pressure that are mediated by sympathetic activation, but it is unknown whether this sympathetic response might also cause imbalance directly affecting cardiac autonomic control. Baroreceptor sensitivity (BRS) measures rapid compensatory regulation of heart rate in response to acute changes in blood pressure. Using a crossover trial of real-world in-vehicle commutes, we tested whether exposure to traffic-related air pollutants (TRAP) affects spontaneous BRS in healthy subjects. Young healthy participants were driven through heavy Seattle, WA traffic for two hours on three different days, each separated by several weeks. On two days, on-road air was entrained into the cabin through the vehicle's factory air vents and sham filters. On another day, the vehicle was equipped with effective filtration. Exposure was double-blinded and participants were randomized to order of exposure. Three minute intervals of continuous blood pressure and pulse intervals were recorded before, during, and up to 24 hours after drive using a Finapres finger pulse waveform device. BRS was calculated as the reduced major axis slope for change in pulse interval per change in blood pressure for rolling 10 second intervals. On filtered days in-vehicle average particle count was reduced by 85%. We used a mixed effects model on the outcome of change from pre-drive BRS measurements, comparing filtered versus unfiltered day at all thirteen time points in nine subjects with measurable BRS, after excluding a single subject with very large changes in BRS. A likelihood ratio test for the effect of filtration on BRS at all time points was not significant ( $p=0.95$ ). At 7 hours after drive start, BRS, relative to pre-drive levels, was on average 1.01 ms/mmHg higher (95% CI:-7.4, 9.4) in unfiltered drives compared to filtered drives. In conclusion, we did not find evidence that TRAP inhalation causes acute change in BRS.

**P02.1700. Consumption of Fruits and Vegetables Might Mitigate the Intermediate-Term Effects of Ambient Particulate Matters on Fasting Blood Glucose, Blood Lipids in Chinese Children**

Suhan Wang

*Suhan Wang<sup>1</sup>, Li Cai<sup>2</sup>, Yajun Chen<sup>2</sup>, Cunrui Huang<sup>1</sup>*

*1. Department of Health Policy & Management, School of Public Health, Sun Yat-sen University, Guangzhou, Guangdong, China. 2. Department of Maternal and Child Health, School of Public Health, Sun Yat-sen University, Guangzhou, Guangdong, China.*

**Abstract:** Background: Evidences on the effects of ambient particles with diameters  $\leq 2.5 \mu\text{m}$  (PM<sub>2.5</sub>) and PM<sub>10</sub> on fasting blood glucose, blood lipids are quite limited among children and the effect modifications by dietary fruits and vegetables remain largely unknown. Objectives: The study aimed to assess the associations between intermediate-term exposure of PM<sub>2.5</sub>, PM<sub>10</sub> and fasting blood glucose, blood lipids in Chinese children. Methods: This study enrolled 4234 children in 5 elementary schools (aged 6-12 years) from 5 districts in Guangzhou, during the period from March, 2017 to May, 2017. Individual PM<sub>2.5</sub> and PM<sub>10</sub> exposures during 6 months before each physical examination were retrospectively estimated by inverse distance weighting interpolation and time-weighted approach according to home address, school address and individual activity patterns. Multivariable linear regression models were used to evaluate the relationships between airborne particulate matters and fasting blood glucose (GLU), total cholesterol (CHO), triglyceride (TG), high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL) after adjusting for other covariates. Results: We found per 10  $\mu\text{g}/\text{m}^3$  increase in PM<sub>2.5</sub> level during the 6-month mean exposure was associated with elevation of 0.26 (95% CI: 0.18, 0.34) mmol/L in GLU. Moreover, with per 10  $\mu\text{g}/\text{m}^3$  increase in PM<sub>10</sub> level during the 6-month mean exposure, significant association with decreased HDL was observed, with the estimated coefficient and 95% CI of -0.04 (95% CI: -0.06, -0.02) mmol/L for HDL. Lower effect estimates were observed among subgroups with higher consumption of fruits and vegetables, lower intake of sugar-sweetened beverages (SSBs). Conclusions: Our study revealed that exposure to ambient PM<sub>2.5</sub> and PM<sub>10</sub> could lead to worsening fasting blood glucose level and blood lipids levels in Chinese children, and lower SSBs intake, higher consumption of fruits and vegetables could mitigate these effects.

## **P02.1710. Acute Effects of Ambient Fine Particulate Matter on Blood Pressure: Results from the Airless Study**

Yiqun Han

*4. Imperial College London, London, United Kingdom.*

*5. Beijing Anzhen Hospital, Beijing, China.*

*6. Duke Kunshan University, Nanjing, China.*

**Abstract:** Background Epidemiological studies have confirmed the link between exposure to fine particulate matter (PM<sub>2.5</sub>) and risk of cardiovascular diseases (CVDs), however, the underlying mechanisms remain unclear. PM<sub>2.5</sub> may increase the risk of CVDs through its effects on blood pressure (BP). Methods Using data from the Effects of AIR pollution on cardiopuLmonary disEaSe in urban & rural reSidents in Beijing (AIRLESS) study, we examine the acute effect of ambient PM<sub>2.5</sub> on BP. During the period of Nov-Dec 2016 (winter) and May-Jun 2017 (summer), 250 participants aged 40-70 years living in an urban or a rural site of Beijing were enrolled. Ambient PM<sub>2.5</sub> concentrations were measured hourly at each site during this period with stationary ambient monitors (BAM/TEOM). Twelve seated BP measurements were taken across 4 visits for each participant (2 visits per season). The association between PM<sub>2.5</sub> and BP was examined with a linear mixed-effects model adjusted for demographic, socioeconomic status (SES) and habitual parameters, ambient temperature and relative humidity. Results The daily mean (standard deviation [SD]) ambient PM<sub>2.5</sub> concentrations during winter and summer campaign were 85.5(78.7) and 48.7(19.2) µg/m<sup>3</sup> in the urban site and 134.0(110.9) and 31.4(14.6) µg/m<sup>3</sup> in the rural site, respectively. Preliminary analyses indicates that increased exposure to ambient PM<sub>2.5</sub> (per interquartile range [IQR] increase: 55.9-57.6 µg/m<sup>3</sup>) during the prior 1-3 days is significantly associated with elevated systolic BP ranging from 1.2 (95% Confidence Interval: 0.7-1.7) to 1.8 mmHg (1.3-2.4), after adjusting for covariates (all P<0.001). Similar results were found for diastolic BP. However, the association between PM<sub>2.5</sub> and BP was no longer statistically significant after further adjustment for ambient temperature and relative humidity. Conclusions PM<sub>2.5</sub> may exert adverse effects on BP, but this positive association was largely explained by temperature and relative humidity.

## **P02.1740. Air Pollution Exposure and Pulmonary Vascular Morphology in the Framingham Heart Study**

**Abstract:** Background: Controlled exposure of rodents to particle pollution has been found to cause pulmonary arteriolar vasoconstriction and increased right ventricular pressure, but few studies have assessed if outdoor pollution exposure affects the pulmonary vasculature in generally healthy adults. Aims: To evaluate associations of long-term exposure to fine particulate matter (PM<sub>2.5</sub>), elemental carbon (EC, an indicator of combustion-related pollution), and distance to a major road with radiographic measures of pulmonary blood volume and distal vascular pruning among community-dwelling adults. Methods: We determined the total blood volume (TBV) of the pulmonary arterial and venous vasculature, and the percent of pulmonary blood volume in vessels with a cross-sectional area less than 5 mm<sup>2</sup> (BV5%, a measure of distal vascular pruning), using an automated CT algorithm among 2,470 Framingham Heart Study chest CT sub-study participants from 2008-2011. We assigned distance to major roadway, average PM<sub>2.5</sub> from 2004-2008 using a spatio-temporal model based on satellite data, and 2004-2008 average EC using a spatio-temporal prediction model using chemical transport data. Linear regression models of each exposure and TBV and BV5% were adjusted for age, sex, height, weight, cigarette smoking, second-hand tobacco, census tract median housing value, cohort (Offspring or 3rd Generation), and date of CT scan. Results: Mean (standard deviation, SD) TBV was 143.1 (31.0) mL and mean (SD) BV5% was 39.3 (4.1) %. Median (interquartile range, IQR) 5-year average exposure was 9.9 (1.3) µg/m<sup>3</sup> for PM<sub>2.5</sub> and 0.44 (0.14) µg/m<sup>3</sup> for EC. In fully adjusted models, living close to a major road, and the 5-year average of PM<sub>2.5</sub> and EC were not associated with TBV or BV5%. Conclusions: We did not observe any associations between exposure to traffic- and combustion-related pollution during adulthood and pulmonary vascular morphology on CT at contemporary pollution levels in the Northeastern United States.

## **P02.1750. Exposure to Ambient PM2.5 during Pregnancy and Preterm Birth in Metropolitan Areas of the State of Georgia**

**Abstract:** Background: A number of studies has pointed to air pollution as an additional factor that could be associated with preterm birth. We assessed in this study the association between exposure to PM2.5 in ambient air during pregnancy and preterm birth in metropolitan areas of the State of Georgia where the rate of preterm birth has been among the highest in the nation over the years. Methods: Birth data were obtained from the National Center for Health Statistics natality dataset. The study population consisted of 53,094 single live births between January 1 and December 31, 2004 in nine metropolitan counties of Georgia. Preterm birth was defined as birth, which occurs before 37 weeks of gestation. County-level air quality index (AQI) data obtained from the U.S. Environmental Protection Agency (EPA) was used to estimate individual exposure levels of PM2.5 for each study participant based on the county of residence for the duration of the pregnancy. A multivariate logistic regression analysis was conducted to assess the association, adjusting for potential confounders. Results: Of the infants whose mothers resided in the nine metropolitan counties of Georgia, 4,543 (8.6%) were preterm birth. A higher rate of preterm birth (9.8%) was observed in infants whose mothers were exposed to ambient PM2.5 with AQI values > 50 than the ones with AQI ≤ 50 (EPA standard for good air quality conditions). Infants with exposure to PM2.5 at the average AQI values greater than 50 during the entire pregnancy were at increased risk of preterm birth (odds ratio: 1.17; 95% CI: 1.09, 1.26), after adjusting for sex of infant, mother's age, race/ethnicity, education, marital status, prenatal care, cigarette smoking, and alcohol consumption. Conclusion: The study provides more evidence on the role of PM2.5 in preterm birth. Reducing exposure to ambient particulate matter, especially in urban areas, for pregnant women would be necessary to improve the health of infants.

## **P02.1760. Air Pollution and Gestational Diabetes in New York City**

*2. Brown University, Providence, RI, United States.*

**Abstract:** Background: Emerging studies suggest a potential association between ambient air pollution and risk of gestational diabetes mellitus (GDM), but results have been heterogeneous. Method: We evaluated the relationship between ambient fine particulate matter (PM<sub>2.5</sub>) and NO<sub>2</sub> and GDM among 256,372 singleton births in New York City in 2008 - 2010. We linked birth certificates to hospital discharge diagnoses and estimated air pollution exposure based on maternal address. The New York City Community Air Survey provided refined estimates of PM<sub>2.5</sub> and NO<sub>2</sub> at the maternal residence. We used logistic regression to estimate the association between exposures to PM<sub>2.5</sub> and NO<sub>2</sub> in the first and second trimester and risk of GDM, adjusting for maternal age, ethnicity, education, Medicaid status, parity, conception year, deprivation index, pre-pregnancy body mass index (BMI) and delivery hospital. Result: GDM was identified in 6.7% of all singleton births. PM<sub>2.5</sub> during the 2nd trimester was positively, but not statistically significantly associated with risk of GDM. Specifically, we found an odds ratio (1.08, 95% CI: 0.99, 1.17) for GDM per 10 ug/m<sup>3</sup> shift in 2nd trimester PM<sub>2.5</sub>. The odds ratio increased to 1.16 (95% CI: 1.05, 1.28) after further adjustment for 2nd trimester NO<sub>2</sub>. PM<sub>2.5</sub> in the first trimester and NO<sub>2</sub> in either trimester were associated with lower risk of GDM, reaching statistical significance in some analyses. Conclusion: There was some suggestion that PM<sub>2.5</sub> exposure during the 2nd trimester is associated with a higher risk of GDM. However, we also found some evidence of negative associations with 1st trimester PM<sub>2.5</sub>, and NO<sub>2</sub> in both trimesters, complicating interpretation.

## **P02.1770. Studying Symptoms and Risk Perception in a Contaminated Site: A Valuable Connection**

**Abstract:** Long-term exposures to air pollution have shown increased risks of developing chronic respiratory diseases, and short-term exposures have been associated with excesses of bronchitis, asthma and respiratory symptoms. A Health Impact Assessment process carried out in the Valley of Agri River (Basilicata, Italy) where is located a crude oil treatment plant, included a population cohort study, a sample study to assess respiratory function and symptoms and risk perception. The main pollutants emitted are NO<sub>x</sub>, H<sub>2</sub>S and VOCs, particularly non-methane hydrocarbons. On 6,795 residents, a sample of 200 healthy subjects, aged 18-74 years, was randomly selected, stratifying by gender, age group and home address in two areas: proximal or distal. For each subject, a spirometry test was performed and a questionnaire administered for characterizing anamnestic history, respiratory symptoms, socio-economic data and risk perception. Measured functional parameters and declared respiratory symptoms were compared between the two areas by using a multivariate logistic regression, adjusted for BMI, smoking, occupational exposure, cardio-vascular comorbidity. Nine subjects showed a bronchial obstruction after bronco-dilator testing. For most of the symptoms a higher risk in the proximal aerea emerged: for cough outside the common colds for some periods of the year and respiratory allergic symptoms associated with eye symptoms, it was statistically significant (OR 2.46 IC95 % 1.02-6.11; OR 2.53 CI95% 1.29-4.94). Risk perception was the same among the subjects residing in the two areas: high perception of exposure to air pollution or to develop asthma was declared in 38% and 67% respectively. Although the small sample size, the excesses of risk emerged for some respiratory symptoms, for which a bias due to risk perception can be ruled out, represent an important result to be used to improve the environment and health sustainability through the implementation of an ad hoc surveillance system.

**P02.1780. Ambient Air Pollution and Emergency Department Respiratory Disease among Adults in Jefferson County, Alabama, U.S.A.**

Meghan Tipre

**Abstract: Background/Aim.** Most air pollution studies model exposure using large geographical units (city/county), resulting in exposure misclassification. In this study we evaluated the relationship between zip-code specific ambient air pollutants and emergency department visits (EDV) for respiratory diseases (RDs) in Jefferson County (JC), Alabama. **Methods.** EDV records for adult patients ( $\geq 18$  years) for RDs were obtained from eight of 11 hospitals in JC from 1999-2009. Data on PM<sub>2.5</sub>  $\mu\text{g}/\text{m}^3$ , PM<sub>10</sub>  $\mu\text{g}/\text{m}^3$ , ozone and speciated compounds from JC monitors were used to model daily exposures for the 67 residential zip codes. Using GAM with Poisson log-link function and splines, risk ratios were computed, adjusting for covariates. Expanded analysis included single-day and moving-average lagged exposure, alternately adjusting for average or range temperature and stratification by seasons. **Results.** A positive association between PM<sub>2.5</sub> (RR, 1.002, 95%CI, 1.002-1.003) and PM<sub>10</sub> (RR, 1.003; 95%CI, 1.003-1.004) and all RD was noted; results were similar for upper respiratory infection (URI) and asthma. Ozone was negatively associated with all RDs (RR, 0.999; 95%CI, 0.998 - 0.999), asthma and URI, limited to winter months (RR, 0.996; 95%CI, 0.995 - 0.997); summer months, (RR, 1.00; 95%CI, 0.999-1.0004). Speciated pollutants including CO, EC, MMO, NH<sub>4</sub>, NO<sub>3</sub>, OC, SO<sub>2</sub>, SO<sub>4</sub>, and TC were positively associated with all RDs, URI and asthma. Strongest associations were noted for 0-8 days moving-average lagged PM and speciated pollutants, particularly NH<sub>4</sub> (RR, 1.022; 95%CI, 1.011-1.033); NO<sub>3</sub> (RR, 1.914; 95%CI, 1.812-2.02), OC (RR, 1.03; 95%CI, 1.023-1.037); and TC (RR, 1.018; 95%CI, 1.012-1.025) and asthma; similar patterns were observed for all RDs and URI. **Conclusions.** PM<sub>10</sub>, PM<sub>2.5</sub> and speciated pollutants increase risk of ED visits for RDs in adults with stronger effects observed with lagged exposures. Possible effect modification by seasons for ozone exposure and RDs were observed.

**P02.1790. Assessment of Hypothetical Nitrogen Dioxide and Particulate Matter Concentration Interventions on Asthma Incidence in Southern Californian Children: A Causal Inference Approach**

Erika Garcia

*Erika Garcia<sup>1</sup>, Robert Urman<sup>1</sup>, Kiros Berhane<sup>1</sup>, Rob McConnell<sup>1</sup>, Frank Gilliland<sup>1</sup>*

*1. Preventive Medicine, University of Southern California, Los Angeles, CA, United States.*

Abstract: Numerous observational studies have linked air pollution with incident childhood asthma. We implemented g-computation, a method based in the counterfactual framework, to estimate the effect on asthma of hypothetical air pollution interventions in a population of Southern California children. We used data from the three cohorts in the Southern California Children's Health Study (recruited in 1993, 1996, and 2002) with prospectively identified incident asthma cases and continuously monitored nitrogen dioxide (NO<sub>2</sub>) and particulate matter  $\leq 2.5 \mu\text{m}$  (PM<sub>2.5</sub>). Multilevel Poisson regression models were developed to estimate the relation between asthma incidence and baseline year annual average pollution concentration, adjusted for potential confounders. For both NO<sub>2</sub> and PM<sub>2.5</sub> we estimated the effect on asthma of 1) remaining at 1993 concentrations-the highest of all three time points-and 2) several hypothetical air quality standards-dynamic interventions where air pollution were reduced to a standard only in communities exceeding the hypothetical standard. All comparisons are to the natural course. The three cohorts included 4,140 children with no history of asthma at baseline and an average of 5.9 years of follow-up (mean baseline age: 9.5 years; 53% female; 55% White; 41% Hispanic). Remaining at 1993 NO<sub>2</sub> levels was estimated to increase asthma incidence by 19.4% (95% CI: 9-32%), whereas implementing hypothetical standards of 30, 20, and 10 ppb were estimated to reduce asthma incidence by 7.2%, 19.5%, and 39.0% respectively. For PM<sub>2.5</sub>, there was an increase of 9.7% (0.8-20%) estimated for remaining at 1993 levels and reductions of 10.8%, 14.7%, and 17.5% for implementing hypothetical standards of 15, 12, and 10  $\mu\text{g}/\text{m}^3$ , respectively. Had NO<sub>2</sub> and PM<sub>2.5</sub> not improved over the study period we expect there would have been more childhood asthma cases; however, had air pollution levels been lower than observed there would have been even lower asthma incidence.

## **P02.1800. Exposure to Smoke from a Coal Mine Fire during Infancy and Lung Function Three Years after the Event**

Fay Johnston

*Jingyi Shao<sup>1</sup>, Graeme Zosky<sup>2</sup>, Graham Hall<sup>3</sup>, Rachel Foong<sup>3</sup>, Amanda J. Wheeler<sup>1</sup>, Marita Dalton<sup>1</sup>, Tierney O'Sullivan<sup>5</sup>, Grant Williamson<sup>5</sup>, Shyamali Dharmage<sup>4</sup>, Fay Johnston<sup>1</sup>*

- 3. Children's Lung Health, Telethon Kids Institute, Perth, WA, Australia.*
- 4. Melbourne University, Melbourne, VIC, Australia.*
- 5. University of Tasmania, Hobart, TAS, Australia.*

**Abstract:** **BACKGROUND:** In 2014, emissions from a fire in an open cut coal mine caused markedly increased concentrations of fine particulate matter (PM<sub>2.5</sub>) in the Latrobe Valley of Victoria, Australia, for approximately six weeks. We aimed to evaluate the lung function of infants who were less than two years of age when exposed to the air pollution from the fire. **METHODS:** Daily average and maximum PM<sub>2.5</sub> exposures were calculated for each participant according to their daily location throughout the fire period. Lung function was measured three years after the fire using the forced oscillation technique. The primary outcomes were z scores for resistance at 5Hz (Rrs5), a measure of airways obstruction, and two indicators of lung stiffness, reactance at 5Hz (Xrs5) and the area under the reactance curve (AX). We used generalised linear models, adjusted for maternal smoking in pregnancy, maternal stress during the fire and maternal education to assess associations between PM<sub>2.5</sub> and lung function. **RESULTS:** We tested 83 children, who had a mean age(SD) of 4.3(0.5) years at the time of follow up. Median [IQR] average PM<sub>2.5</sub> exposure was 8.9 [7.2-19.3] µg/m<sup>3</sup> and maximum PM<sub>2.5</sub> was 29.0 [16.1-49.9] µg/m<sup>3</sup>. The mean(SD) z scores of participants were Rrs 0.6 (0.8), Xrs -0.8(0.9) and AX 0.7(0.9). A 10µg/m<sup>3</sup> increase in average PM<sub>2.5</sub> exposure during the fire period was independently associated with z scores for Rrs 0.18 (95%CI 0.01,0.34, p=0.038), Xrs -0.20 (-0.36, -0.04, p=0.015), and AX, 0.25 (0.07 to 0.42, p=0.006). In addition, maternal smoking in pregnancy was strongly associated with measures of reactance Xrs5: -1.25 (-1.75, -0.76, p=0.000) and AX: 0.97 (0.42, 1.51, p=0.001). **CONCLUSION:** Exposure to a period of reduced air quality during infancy was associated with reductions in lung function measured three years after the event. The possible long term clinical implications or reversibility of these changes is not known. Further research is required to validate these findings.

**P02.1810. Interaction Effects of Air Pollution and Influenza Vaccination on Allergic Respiratory Diseases and Symptoms in Chinese Children: The Seven Northeast Cities Study**

Kangkang Liu

*Kangkang Liu<sup>1</sup>, Guanghui Dong<sup>1</sup>*

*1. School of Public Health, Sun Yat-sen University, Guangzhou, Guangdong, China.*

**Abstract:** Background Few studies explore the effectiveness of influenza vaccination in children who expose the long-term high-intensity air pollution. Therefore, the aim of this study is to evaluate the potential roles of interaction effects between air pollutions and influenza vaccination on children's allergic respiratory diseases and related symptoms. Methods A cross-sectional survey was conducted on 56,137 school-aged children from 27 administrative districts in seven cities in north China. Parents of the children helped to complete questionnaires which contain the social demography characters, histories for respiratory symptoms and illness of children, the environment for dwelling, school, or other activities areas, the situation of influenza vaccination and other risk factors. A multi-level logistic regression model was used to analyze the roles of interaction effects between influenza vaccine and air pollution on children's respiratory health. Results Among the vaccine groups compared with the unvaccinated group, the lower incidence rates were appeared in the symptoms of asthma, current diagnosis of asthma, wheezing, cough, phlegm and rhinitis. The significant effects of interactions between particulate matters (PM) and influenza vaccine inoculation for PM1.0 and PM2.5 on children's symptoms of asthma were found ( $P < 0.01$ ). The associations between PM2.5 exposure and asthma were weaker in the children with influenza vaccination (OR: 1.213, 95%CI: 1.159, 1.269) than the children without influenza vaccination (OR: 1.332, 95%CI: 1.280, 1.387). The interaction effects between PM2.5 and influenza vaccine among boys with current asthma were significant ( $P = 0.023$ ). Conclusions The potential effects of interactions between air pollutions and influenza vaccine inoculation on children's respiratory health were found in this study. The differences of the susceptibility of asthma between boys and girls were found when the children exposed air pollutions and influenza vaccination.

**Abstract:** **BACKGROUND:** Air pollution is a key global public health challenge. The Mexico City Metropolitan Area (MCMA), a megalopolis of 23 million people, exceeds the WHO's recommendation for the annual average of PM2.5 level. **AIM:** To estimate the association of PM2.5 exposure and acute respiratory tract symptoms (ARTS) in children, and with ischemic heart disease (IHD) and hypertension (HT) in adults, in a representative sample of the MCMA population. **METHODS:** Participant health information was obtained from the National Survey of Health and Nutrition 2006 and 2012. Exposure to PM2.5 was estimated using 1, 3, 7, 14, 30 and 365-day averages before day-of-interview from the city monitoring network (MNW) and a satellite-based model (SM). We used logistic regression models, adjusted for age, sex and socio-economic status considering the sampling design **RESULTS:** The sample represented 3.1 and 3.6 million children and 12.7 and 13.8 million adults in 2006 and 2012, respectively. Annual PM2.5 estimation was higher using MNW vs SM (SM: 2006: 25.9; 2012: 24.8  $\mu\text{g}/\text{m}^3$  vs MNW 2006: 29.0; 2012: 26.7  $\mu\text{g}/\text{m}^3$ ). We saw decreased annual averages with both estimation methods, but they both double the Mexican standards. We found a positive association between 2-week PM2.5 exposure and ARTS, with both exposure methods, statistically significant in 2006 using the MNW (OR: 1.46, 95%CI: 1.00-2.15. Positive associations with IHD and previous year exposure were estimated using MNW, however they were non-significant for both surveys. The results using SM were inconclusive. For HT and previous year exposure, we observed a positive association using SM in both surveys, significant for 2012 (OR: 2.54; 95%CI: 1.12-5.77). The estimates using MNW were inconclusive. **CONCLUSIONS:** There were positive associations between PM2.5 exposure and acute and chronic diseases. For acute outcomes, MNW estimations seems to better capture the daily variability in PM2.5, whereas for chronic diseases both methods can be useful.

**Abstract:** Background: Respiratory syncytial virus (RSV) ranks first among the causes of acute lower respiratory infections in children. The most common clinical syndrome associated with RSV infection is bronchiolitis (RSV-B). Air pollution might influence the inflammatory cascade that brings to RSV-B. Aims: To investigate the association between PM10 exposure and the risk of hospitalization for RSV-B. Methods: We selected hospital discharge records (HRD) with ICD-9-CM code 466.11, referring to infants <1 year of age, and occurring in the epidemic seasons of 2012-2013 in Lombardy, Italy. Each case was assigned daily PM10 and apparent temperature (AT) levels of the provincial capital city of residence. Different time windows were considered: single days preceding hospitalization (lag 0 to 30), their average estimates (lag 0-1 to 0-30), the weeks preceding hospitalization (week 1 to 4). We applied negative binomial regression models adjusted for AT and season to the daily counts of hospital admissions in each province. Random effects meta-analyses of province-specific estimates were performed to obtain regional values. Results were expressed as incidence rate ratios (IRR) and 95% confidence intervals (95%CI) per 10µg/m<sup>3</sup> increase in PM10 concentration. Results: 2,814 HRD were included (males = 55%). We observed an increased hospitalization risk of 6% at lag 0 and of 7% at lag 1 (95%CI: 1.03-1.10 for both). IRR ranged from 1.03 to 1.05 between lags 2 and 11, and no risk increase was observed from lag 12. Analyses on averaged daily lags showed increased risks in the two weeks preceding hospitalization, with IRR from 1.08 (1.04-1.12) at lag 0-1 to 1.15 (1.08-1.23) at lag 0-13. When considering weekly lags, a 6% (1.01-1.12) and a 7% (1.02-1.13) increased risks were observed during weeks 1 and 2, respectively. Conclusions: Our study improved the body of evidence on the association between short- and medium-term PM10 exposures and the risk of hospitalization for RSV-B among infants.

## **P02.1840. Estimating Asthma, Myocardial Infarction, and Heart Failure Hospitalizations and Emergency Room Visits in New York City from PM2.5 Exposure Using a Bayesian Modeling Approach**

Eric Hall

*Eric S. Hall<sup>1</sup>*

*1. Office of Research and Development, US Environmental Protection Agency, Durham, NC, United States.*

Abstract: Fine particulate matter has been shown to influence the frequency and severity of respiratory and cardiovascular diseases, and also increases inflammatory proteins and heart rate variability (HRV). The typical air pollution-focused health study uses concentration data from the nearest ground-based air quality monitor(s), which have missing data on the temporal scale due to filter collection schedules (once every 3 days or once every 6 days), and on the spatial scale due to monitor placement. To overcome these data gaps, this project used a Bayesian model to generate estimates of PM2.5 in areas with and without air quality monitors. This was achieved by combining PM2.5 concentrations measured by monitors, PM2.5 concentration estimates derived from satellite aerosol optical depth (AOD) data, and Air Quality model predictions of PM2.5 concentrations, into ambient concentration surfaces covering selected geographic areas. The objectives of this study were to: 1) demonstrate that the inputs to the model could include AOD data in addition to measurement data from monitors and modeling estimates from air quality models, and; 2) determine if inclusion of AOD surfaces in Bayesian model algorithms resulted in air pollutant concentration surfaces which accurately predicted hospital admittance and emergency room visits for MI, asthma, and HF. The focus was the New York City, NY metropolitan and surrounding areas from 2004-2006. The results showed PM2.5 exposures above the National Ambient Air Quality Standard (NAAQS) value (12 mg/m<sup>3</sup>) were associated with increased risk of asthma, MI and HF. Estimates derived from concentration surfaces incorporating AOD had a similar estimate of risk as compared to those derived from combining monitor and CMAQ data alone. This study demonstrated that PM2.5 concentrations from satellite data can be used to supplement PM2.5 monitor data and air quality model estimates of PM2.5 in assessing risk associated with three common health outcomes.

Abstract: The 2016 wildfire in Fort McMurray forced the evacuation of all 88 000 residents, and destroyed 15 % of the town's built structures. Re-entry was delayed after initial tests revealed elevated concentrations of the toxic elements Cr, As, and Sb and polycyclic aromatic hydrocarbons (PAHs) in fire ashes. No studies exist so far that investigate if and how long wild-fire derived pollutants are retained in indoor environments and pose a long-term health risk to residents. We report initial results from a house dust sampling campaign carried out 14 months after the fire. We compare dust samples from 62 houses to urban and forest-floor ash collected during the Fort McMurray wildfire, background studies, and regulatory guidelines (Alberta Tier 1 guideline for residential soils). Concentrations of Cr, As, and Sb in Fort McMurray (geom. mean 45, 4.2, and 6.5 ppm) were comparable to those in background studies (geom. mean 101, 7.7, and 5.5 ppm). Our dataset, however, showed a higher variability of Sb concentrations, such that the most polluted houses of our study (95%-percentile: 46 ppm) exhibited significantly higher concentrations than in the background study (15 ppm). Pollutant concentrations in ash samples differed between urban and rural areas. Urban areas exhibited high concentrations (200-3000, 100-1300, and 20-300 ppm; n=3) that exceeded regulatory guidelines (64, 17, and 20 ppm), while concentrations in forest-floor ash samples were typically below those found in house dust samples (7-300, 1-12, and 0.1-3 ppm; n=5). We also report high levels of volatile PAHs (naphthalenes) in both fire ash and dust in homes heavily damaged by the wildfires 14 months after the event. Overall, our results indicate that very high concentrations of pollutants can be found in ashes from urban, but not rural, areas; however, our data do not provide evidence that all pollutants persist in house dust over extended periods of time.

**P02.1860. Evaluation of LPG Use as a Clean Cooking Fuel in South West Cameroon: Findings from Community Surveys from the LPG Adoption in Cameroon Evaluation (Lace) Studies**

Daniel Pope

*Bertrand Hugo Mbatchou Ngahane<sup>1</sup>, James Higerson<sup>2</sup>, Lirije Hyseni<sup>2</sup>, Sara Ronzi<sup>2</sup>, Nigel Bruce<sup>2</sup>, Debbi Stanistreet<sup>2</sup>, Elisa Puzzolo<sup>3</sup>, Dan Pope<sup>2</sup>*

*1. Internal Medicine, Douala General Hospital/University of Douala, Douala, Cameroon.*

*2. Department of Public Health & Policy, University of Liverpool, Liverpool, United Kingdom.*

*3. The Global LPG Partnership, London, United Kingdom.*

**Abstract:** Background: Most households in Cameroon rely on solid fuel for cooking. The government has launched a Master Plan to increase LPG use from <20% to 58% by 2035 to address deforestation and energy security issues. To understand how to support communities transition from solid fuel to LPG, LACE surveys assessed household characteristics and perceptions of LPG in different fuel using groups. Methods: After rapid census, 320 households from rural and peri-urban communities in SW Cameroon were randomly selected into 4 fuel-use groups: exclusive LPG (n=51), primary LPG (n=52), mixed LPG and biomass (n=113) and exclusive wood (n=104). Surveys collected information on (i) household characteristics and fuel use practices, (iii) perceptions of LPG and (iv) experience of health issues and burns. Results: Amongst LPG users, distance from retailer (refills) impacted on more exclusive use (travel > 5km: 15% of LPG exclusive/ primary users vs 24% of LPG mixed). Greater income, education and a younger age were associated with increasing LPG use (p<0.05). Perceptions of LPG as a cooking fuel differed by amount of LPG use. 85% of LPG exclusive users reported LPG could be used for most foods compared to 40% of wood exclusive users (p<0.05). Increasing LPG use was associated with increased reporting of LPG as a clean and fast fuel and cost was less of an issue. In all groups, LPG was perceived as potentially dangerous (>75% reporting). The occurrence of cough and phlegm was low in all groups, whilst a higher proportion of exclusive wood users reported sore eyes (60% vs 29% (LPG exclusive) p<0.005) and burns (23% vs 10% p=0.007) . Conclusion: Potential barriers to adoption and more exclusive use of LPG include its perceived ability to cook most foods, perceptions over its safety and distance from retail outlets. Household income is a strong indicator of usage. Education strategies (health and safety) and financial support mechanisms (e.g. microfinance) could help scaling LPG adoption

## **P02.1870. Estimating Fine-Scale Temporal and Spatial Characteristics of SO<sub>2</sub> Exposures Using U.S. EPA's Air Pollutants Exposure (APEX) Model**

Graham Glen

*2. OAQPS, US EPA, Durham, NC, United States.*

**Abstract:** The U.S. EPA Air Pollutants Exposure Model (APEX) is a stochastic model simulating inhalation exposure using fine-scale population demographics, human activity and physiology, time series of ambient chemical concentrations, and parameterizations of chemical infiltration into microenvironments. For a recent high-resolution population-based exposure assessment of three U.S. urban areas (Tulsa, OK; Indianapolis, IN; Fall River, MA), we used APEX to estimate the percent of the study population experiencing 5-minute SO<sub>2</sub> exposures at or above selected benchmark levels (100-400 ppb, 100-ppb increments) and the resultant lung-function decrements. We generated complete time series of 5-minute ambient SO<sub>2</sub> concentrations at thousands of receptors in each study area, combining modeled hourly concentrations with continuous 5-minute ambient measurements for 2011-2013, then adjusted to just meet the current national ambient air quality standard. We developed new model input data and algorithms as a function of sex and age to support the high resolution of this assessment, including data on demographics, commuting patterns, and asthma prevalence at the level of U.S. Census blocks, and algorithms to estimate short-term breathing rates and energy expenditure. Results showed notable differences in SO<sub>2</sub> exposure by location, with fewer elevated exposures and health risks estimated in Tulsa, OK relative to the other study areas. An important factor in these results is the lower numbers of people estimated to live or work in areas of higher SO<sub>2</sub> concentrations in the Tulsa scenario relative to the other scenarios. These results indicate the importance of the accuracy and spatiotemporal resolution of the air concentration and population data in estimating population exposures and health risks to inform policy decisions.

## **P02.1880. Infant Exposures to PM-Bound Metals Associated with Household Air Pollution and Cooking**

Ryan Chartier

*Ryan T. Chartier<sup>1</sup>, Seung-Hyun Cho<sup>1</sup>*

*1. AQ&E, RTI International, Research Triangle Park, NC, United States.*

**Abstract:** Background Around 3 billion people globally rely on solid fuels for their household energy needs. Exposure to high levels of the resultant household air pollution (HAP) has been linked to a plethora of adverse health outcomes. Until the recent development of the MicroPEM and Enhanced Children's MicroPEM, it was not possible to accurately quantify the levels, patterns, and composition, of personal HAP exposures of small children. Methods The study was carried out at the Karonga Prevention Study, Malawi, where children born in homes with improved (Philips HD4012) and 3-stone stoves were followed at 6 weeks and 6 months. Nasopharyngeal swabs were collected and 48-hour real-time and integrated PM<sub>2.5</sub> exposures were measured using the RTI MicroPEM. Following gravimetric analysis of PM<sub>2.5</sub> mass, the filters were analyzed for 33 metals with x-ray fluorescence spectroscopy. Results Valid personal exposure measurements are available on 694 children. Overall, we did not observe a difference in geometric mean PM<sub>2.5</sub> exposure levels between children in homes with a traditional stove compared to those in intervention homes ( $p=0.153$ ,  $53.4$   $95\%CI[49.9,57.1]\mu\text{g}/\text{m}^3$ ,  $48.0$   $[42.1, 54.6]\mu\text{g}/\text{m}^3$ ; respectively) ( $p=0.153$ ), except when cooking occurred indoors ( $p=0.002$ ,  $91.8$   $[75.1, 112.4]\mu\text{g}/\text{m}^3$ ;  $54.7$   $[42.4, 70.4]\mu\text{g}/\text{m}^3$ ; respectively). Preliminary data show that children in homes using the Philips stove were exposed to higher levels of Aluminium (170%), copper (185%), chromium (240%), and iron (187%), than children living in homes using a traditional 3-stone stove. Conclusions Exposure to PM-bound metals have been shown to have immunotoxic effects in animal models and exposures to high levels of PM-bound metals such as iron have correlated with increased rates of severe pneumonia in some populations. To our knowledge, this is the first study to report direct infant personal exposures of PM-bound metals associated with household air pollution; the first step towards quantifying potential health impacts.

## **P02.1900. Symptoms and Behaviors Related to Wildland Fire Smoke Exposure: Data from the EPA Smoke Sense Citizen Science Smartphone Application**

Steven Prince

- 2. NHEERL, Environmental Protection Agency, Durham, NC, United States.*
- 3. ORD, Environmental Protection Agency, Durham, NC, United States.*

**Abstract:** Exposure to smoke from wildland fires is associated with an increased incidence of health burdens and thus warrants further study to understand behavioral patterns related to exposure reduction efforts. We examine the feasibility of using EPA's Smoke Sense smartphone application (iOS and Android) to engage users during smoke events and investigate the range of actions taken in relation to smoke exposure and symptoms experienced. Users of the application reported on the presence or absence of a smoke event in their area, symptoms they experienced and number of days, averting actions (protective measures such as avoiding outdoor recreational activity, staying indoors, using a respirator mask, using an air cleaner, etc.), and mitigating actions (taking medication or seeking medical care) they may have taken. Users reported symptoms (across four categories: eyes and ears, respiratory, cardiovascular, other) and their severity (e.g. did they need to take mitigating action). The majority reported previous health conditions relevant to the effects of air pollution. Among those who experienced smoke events, the average number of symptom days was 2.5 compared to 0.8 during non-smoke periods, and the odds of reporting symptoms were 4.1 to 11.8 times greater than during non-smoke periods. Averting and mitigating actions have varying "costs," including financial, time, effort, social etc. For example, users could report no averting actions (no costs), staying indoors (some cost), avoiding daily activities such as work (high cost) or seeking medical care (high cost). We examine the extent to which averting and mitigating actions impact symptom severity and the extent to which cost impacts the likelihood of adopting these actions. Using regression models and mediation analyses, we describe relationships between smoke exposure, averting and mitigating actions, and symptoms experienced. Disclaimer: The views expressed do not necessarily reflect the views or policies of the U.S. EPA.

## **P02.1910. Volatile Organic Compounds in Homes in Shanghai, China: Identification of Pollutant Sources and Impact of Air Purifier Use on Pollutant Levels**

Christina Norris

*Christina Norris<sup>1</sup>, Lin Fang<sup>4</sup>, Karoline Johnson<sup>1</sup>, James J Schauer<sup>2</sup>, Junfeng (Jim) Zhang<sup>3</sup>, Yinping Zhang<sup>4</sup>, Michael Bergin<sup>1</sup>*

*3. Nicholas School, Environmental Science and Policy Division, Duke University, Durham, NC, United States. 4. Department of Building Science, Tsinghua University, Beijing, China.*

**Abstract:** Although Chinese residents spend the majority of their time indoors, pollutants in the indoor environment have not been studied as extensively as their outdoor counterparts. This is especially true of volatile organic compounds (VOCs), many of which are associated with adverse health outcomes and have indoor sources. For this study, 20 homes with asthmatic children were recruited from the suburbs of Shanghai, China. This study explored pollutants and the impacts of air filtration on pollutant levels. Air purifiers were installed twice, for two-week periods, in the child's bedroom - once with all levels of filtration (pre-filter, HEPA filter, carbon filter) and again with only a coarse pre-filter. During both periods, indoor and outdoor samples were collected simultaneously on Tenax and DNPH tubes in the early morning using pump packages developed at Duke University. Of the 900+ compounds detected, 117 were detected in 10 or more samples. Total VOCs were higher indoors than outdoors in most homes under both conditions (median values [in mg m<sup>-3</sup>] - sham, in/out: 235/59; true, in/out: 119 /77). There was a significant reduction in indoor-outdoor ratios during true compared to sham filtration indicating a potential benefit of filtration (median reduction: 36%, range: -224%, 96%). Non-negative matrix factorization was used to identify groupings of compounds (features) illustrative of sources. Of the features identified, two indicate outdoor sources with certain compounds detected in most outdoor samples but seldom detected indoors. The other three features point to indoor sources. Preliminary analyses indicate compounds detected predominantly indoors may relate to cleaning or personal care products, although analysis is ongoing. This work provides new insight to potentially harmful compounds in Chinese homes, as most previous studies have focused on assessment of total VOCs or select, well-characterized VOCs including BTEX and formaldehyde.

## **P02.1920. Ultrafine and Fine Particulate Matter Levels over Resurfacing Operations at Skating Arenas**

Sunil Varughese

*Sunil C. Varughese<sup>1</sup>, Kelly Sabaliauskas<sup>2</sup>, Seema Sharma<sup>1</sup>, Chantal Burnett<sup>1</sup>, Tracy Kirkham<sup>3</sup>*

*2. Toronto Public Health, Toronto, ON, Canada.*

*3. Occupational and Environmental Health, DLSPH, University of Toronto, Toronto, ON, Canada.*

**Abstract:** Background: Ice arenas are a unique public indoor space where there is extensive use of combustion engines combined with an exercising population. This pilot study seeks to identify ultrafine particle (UFP) levels and fine particulate matter (PM<sub>2.5</sub>) in indoor ice arenas across resurfacing operations. Ice making is a time-consuming and expensive process. In order to preserve the ice and ensure a smooth surface, arena operators resurface ice based on usage. Ice resurfacing involves driving a resurfacing machine over the surface of the ice as it simultaneously scrapes off a thin layer of ice and fills scratches with water, resulting in a smooth and even ice surface. Pollutants can be trapped near the ice from stagnant air flow due to a combination of boards and glass surrounding the ice and a thermal inversion which keeps colder air near the ice surface.

**Methods:** UFP and PM<sub>2.5</sub> measurements were continually collected using a TSI P-Trak and a TSI Dusttrak DRX. Samples were run indoors before, during and for approximately 20 minutes after one resurfacing event to capture changes in particle levels throughout the event and outdoor background measurements were taken. Sampling was conducted on two separate days in 12 arenas, once in the morning and once in the afternoon. Arenas were selected that differed in their ventilation characteristics and resurfacing equipment (7-propane, 3-natural gas, 1-gasoline, 1 electric).

**Results:** Mean resurfacing time was 9.1 minutes (range 6-16) and was performed hourly during high arena usage. Peaks in UFP were typically observed 10 minutes post resurfacing with a mean increase in peak UFP from pre- to post- resurfacing across arenas of 65% (range 13-400%). However, PM<sub>2.5</sub> levels were not elevated following resurfacing operations. **Conclusion:** The poster will provide results on changes in UFP levels by fuel type of resurfacer.

## **P02.1930. A New Method, $\eta$ -Indoor Particle Age Method, of Estimating Indoor Airborne SVOC Concentrations**

Yinping Zhang

Yinping Zhang<sup>1</sup>, Jianping Cao<sup>1</sup>, Jinhan Mo<sup>1</sup>, Zhiwei Sun<sup>1</sup>

*1. Department of Building Science, Tsinghua University, Beijing, China.*

**Abstract:** To appropriately assess exposure to indoor semi-volatile organic compounds (SVOCs), a convenient but relatively accurate method considering the non-equilibrium sorption behavior between their gas-phase concentration ( $C_g$ ) and particle-phase concentration ( $C_{sp}$ ) is needed. There are two reasons: (1) the equilibrium model frequently used in previous studies may result in significant errors because the time that particles stay in the indoor air is often much shorter than the critical time for  $C_g$ - $C_{sp}$  equilibrium; (2) several dynamic models in the literature took the mean residence time of indoor airborne particles as the time duration of the mass transfer between SVOCs and particles in the indoor environments, which may obviously reduce their accuracy because residence time varies among individual particles, and the  $C_g$ - $C_{sp}$  relationship and residence time are not linearly correlated. Therefore, we put forward a new concept, indoor particle age (the time that airborne particles have spent since entering the room), and develop a method, named as " $\eta$ -indoor particle age method" to address the aforementioned problems. The  $C_{sp}/C_g$  value can be obtained by multiplying the equilibrium result by a modification factor,  $\eta$  (which is a function of indoor particle age, particle size distribution and the critical time for  $C_g$ - $C_{sp}$  equilibrium). The  $\eta$ -indoor particle age method can reduce the relative errors of the equilibrium model by over 1000% for many scenarios, and the existing dynamic models by over 30%, which are preliminarily supported by the experimental results in the literature. In addition, the method is useful in determination of the partition coefficients between indoor particles with different sizes and various gas phase SVOCs.

**P02.1950. Change in Indoor Formaldehyde Concentration and Prevalence of Subjective Symptoms in Medical Students Exposed to Formaldehyde during Gross Anatomy Dissection Classes, and Effectiveness of Exposure Prevention by Wearing Personal Protective Equipment**

Mihoko Mori

*Mihoko Mori<sup>1</sup>, Tsuyoshi Saga<sup>2</sup>, Yoko Tabira<sup>2</sup>, Koichi Watanabe<sup>2</sup>, Koh-ichi Yamaki<sup>2</sup>, Tatsuya Ishitake<sup>1</sup>*

*1. Department of Environmental Medicine, Kurume University School of Medicine, Kurume, Fukuoka, Japan.*

*2. Department of Anatomy, Kurume University School of Medicine, Kurume, Fukuoka, Japan.*

Abstract: In Japan, medical students are exposed to formaldehyde (FA) during gross anatomy dissection classes. Students complain various subjective symptoms such as mucous membrane irritation symptoms and unidentified complaints. We have taken ongoing measures to decrease FA exposure at our university. Wearing personal protective equipment (PPE) such as gas masks and safety glasses is effective in reducing exposure to FA, as shown by previous studies. This study evaluated correlation with FA concentration in an anatomy practical room and prevalence of 14 symptoms where students experienced during the anatomy practice. Furthermore, we evaluated the effectiveness of prevention by wearing PPE. We conducted brief questionnaire surveys after every practice with second-year students participating in an anatomy class in 2016, concerning 14 subjective symptoms, including eye, nose, and throat complaints, as well as unidentified complaints, and whether or not to wear PPE, their sleep duration of the previous night, the number of cigarettes smoked, and their physical condition during the day in question. And, we measured indoor levels of FA during every practice. Subjective symptoms were classified into four categories. Those answering "very severe" or "severe" were classified as having subjective symptoms. There were significant correlations between FA concentration in an anatomy practical room and prevalence of some symptoms where students experienced during anatomy practice. And we found a certain level of effectiveness of prevention by wearing PPE during the practice. We need to recommend to wearing PPE during the practice, especially at high level of indoor FA concentration.

## **P02.1960. Evaluation of Monitoring Data of Persistent Organic Pollutants for Identification of Sources, Pathways and Trends of Environmental and Human Exposure**

Gerlinde Knetsch

*Gerlinde Knetsch<sup>1</sup>*

*1. Chemical Safety , German Environment Agency, Dessau-Rosslau, Germany.*

Abstract: Monitoring data is essential for investigate sources, pathways and the exposition of environment and human beings. The paper concerns with persistent organic pollutants (POPs) and the impact to human health via the food chain. In recent years food monitoring of dioxin-like Polychlorinated Biphenyls (dl PCBs) and non-dioxin-like Polychlorinated Biphenyls (ndl PCBs) has been intensified in Germany. Reasons for this, it has been increasingly found that particularly farm animals from extensive farming (cattle, sheep, laying hens) or the food they produce, partially exceed the EU maximum levels for the sum of dioxins and dl-PCBs (WHO-PCDD/F-PCB-TEQ). The impact is originated come largely from the environment. Humans essentially ingest PCDD/F and PCBs from fatty animal-derived foods such as meat, dairy and eggs and fishery products. Through historic uses PCBs predominantly were released to the environment compartments as well as to feeding stuff for animals. The properties of bioaccumulation and persistence of dl-PCB results in an enrichment in the food chain. The behaviour of other substitute substances namely short-chain chlorinated parafins (SCCP), polybrominated diphenyl ethers (PBDE) and hexabromocyclododecane (HBCD) were investigated in this context, in order to comprehend their ubiquitous appearance well as the mechanisms and pathways of dispersal. Are there analogies to the issues of PCBs? The presentation will give a survey about the congener profile data collected to identify possible causes for contamination of environmental samples, technical products but also for food. The benefit of the data collection in the POP-Dioxin-Database of Germany consists in the harmonisation of the data, an abundance of supporting of metadata and generation of profiles. The presentation will conclude with an outlook on future activities of the German Environment Agency, e. g. concerning data sharing in context of Information Platform for Chemical Monitoring (IPChem).

## **P02.1970. Short-Term PM2.5 Exposure and Cause-Specific Mortality in China: A Multicounty Time-Series Analysis**

Chen Chen

*Chen Chen<sup>1</sup>, Tiantian Li<sup>1</sup>, Xiaoming Shi<sup>2</sup>*

*1. Department of Environmental Health Risk Assessment, Institution/Organization: National Institute of Environmental Health, Chinese Center for Disease Control and Prevention, Beijing, China, Beijing, China.*

*2. National Institute of Environmental Health, Chinese Center for Disease Control and Prevention, Beijing, China, Beijing, China.*

Abstract: Efforts to understand the acute effects of PM2.5 concentration at low levels on health have a great deal of multiple centers epidemiologic research in developed countries. In order to identify how short-term exposed to PM2.5 can harm human health, it is crucial to estimate the exposure-response relationships at higher exposure. People in China have been exposed to particularly higher levels and few studies conducted in China showed different magnitudes of PM2.5 acute effect. Considering the severe pollution situation and the inconsistent effects, it is worth initiating more in-depth studies to understand of the acute effects of PM2.5 in China. Applying a county-specific quasi-Poisson regression in 59 counties over China Mainland, we estimated PM2.5 effects on death of all nature cause and 11 specific causes during 2013 to 2015. Then we pooled the county-specific results across China using a random effects meta-analysis. We found a 10 µg/m<sup>3</sup> increment in PM2.5 at lag 0-1 day was significantly associated with a 0.14% (95% CI, 0.03-0.25) increase in the risk of all nature cause, a 0.30% (0.01-0.58) increase in stroke, a 0.28% increase (0.07-0.50) in respiratory disease, a 0.29% (0.03-0.55) increase in chronic lower respiratory disease, and a 0.30% (0.03-0.56) increase in COPD. Associations for respiratory causes of death were larger than for cardiovascular causes, while the magnitudes were less than that reported in developed counties. These findings complemented evidence related to exposure-mortality relationships at the higher end of PM2.5 exposure as well as benefited to arrange strategies of health protection targeted to sensitive disease.

## **P02.1980. Effect of Reducing Fine Particle Concentration after Use of Air Purifiers in Hospital: Preliminary Results**

*5. Ewha Womans University School of Medicine, Seoul, Korea (the Republic of).*

Abstract: Most hospitals have air-conditioning facilities, but many people are moving, and there are many indoor air pollutants such as fine particle. In this study, air purifier is installed in hospital ward to investigate the improvement of indoor air pollution. We installed 25 air purifiers in 4th floor ward of a university hospital in Seoul, Republic of Korea. The air purifier filter is turned on and off at intervals of 4 weeks, and the indoor fine particle concentration is continuously measured through the dust sensors of the air purifiers. We obtained the outdoor fine particle data from the nearest Air Korea measuring station. We compared indoor fine particle concentrations before and after using the air purifier and compared those after stratification of the types of place (single rooms, rooms with five or six beds, nurse stations, and patient rest room). We also analyzed the average difference and correlation between indoor and outdoor fine particle concentrations. After the use of air purifiers, the difference of indoor and outdoor fine particles concentrations are larger and the correlation between outdoor and indoor fine particle was also lower than that before the use of air purifiers. The average difference of indoor fine particle before and after use of air purifier was about 3.46-5.68  $\mu\text{g}/\text{m}^3$ . Among the four types of places, the nurse stations had the highest concentration of fine particles, the lowest patient rest room, and there was a difference between the groups. Despite having air conditioning facilities in the hospital, indoor fine particle concentration was lower when air purifiers was used than before use of air purifiers. Particularly in places where people are moving a lot in the ward, fine dust is high. Therefore, additional efforts are needed to lower the concentration of fine particle in hospitals such as use of air purifiers.

**P02.2000. Associations between Infant Birth Weight and Seasonal Variations in PM2.5 Exposure during Pregnancy: A Prospective Cohort Study in a Rural Community in China**

Yan Li

Yan Li<sup>1</sup>, Xiaoxiao Song<sup>1</sup>, Xia Xiao<sup>1</sup>, Edmund Seto<sup>2</sup>, Kek-Khee Loo<sup>3</sup>, Jie Wu<sup>1</sup>, Rui Ma<sup>1</sup>, Yan Zhang<sup>4</sup>

2. University of Washington, Washington, WA, United States.

3. University of California, Los Angeles, Los Angeles, CA, United States.

4. Yunnan Maternal and Child Health Hospital, Kunming, China.

**Abstract:** Background: Exposure to PM2.5 (fine particulate matter) pollutants in pregnancy has generally been found to be associated with infant low birthweight. In rural China, exposure of pregnant women to PM2.5 from indoor coal or wood-burning heaters, stoves and second-hand smoke is expected to have seasonal variations that may have implications on the birth weight of the offspring. Methods: In a prospective pregnant woman cohort study, 380 pregnant women carried a Portable Particle Monitor to measure 24-hour individual exposure to PM2.5 over a period of 5-7 days at first (T1), second (T2) and third trimester (T3) time points. The questionnaires to women were conducted simultaneously. Newborn were weighted by standard scale at birth. Latent Variable Growth Curve Modeling was used to elucidate the effects of seasonal variation to PM2.5 exposure in the course of pregnancy on the birth weight. Four groups were compared based on the season when the mother was in first trimester. Results: The average PM2.5 exposure throughout pregnancy were 27.2, 26.3, 28.3, and 30.9  $\mu\text{g}/\text{m}^3$  in four groups (their first trimester in Spring, Summer, Autumn and Winter), respectively. Different groups revealed special associational patterns. Intercept factors were -25.8, -51.3, -27.0, and -43.1 for mothers in first semester in Spring, Summer, Autumn and Winter respectively and slope factors were 0.8, -3.7, 8.4, and 8.2, respectively. Mothers in first trimester in Summer had newborns with the lowest birth weight with an increase of one unit of PM2.5 exposure being associated with a decrease in 51.3g in birth weight. Conclusions: PM2.5 exposure was associated with low birth weight across all 4 groups. Mothers who were not exposed to winter had newborns with the highest birth weights. Increased exposure to PM2.5 in the cold seasons may cause the decrease of birth weight and was associated with low birth weight.

## **P02.2010. Risk of Respiratory Hospital Admissions in the Vicinities of Large-Scale Composting Facilities in England**

Aina Roca Barceló

*Aina Roca Barceló<sup>1</sup>, Philippa Douglas<sup>1</sup>, Daniela Fecht<sup>1</sup>, Anna Freni Sterrantino<sup>1</sup>, Marta Blangiardo<sup>1</sup>, Ben Williams<sup>2</sup>, Enda Hayes<sup>2</sup>, Anna Hansell<sup>1</sup>*

*1. UK Small Area Health Statistics Unit (SAHSU), MRC-PHE Centre for Environment and Health, School of Public Health, Imperial College London, London, United Kingdom.*

*2. Air Quality Management Resource Centre, University of the West of the West of England, Faculty of Environment and Technology, Bristol, United Kingdom.*

**Abstract:** Background Biological aerosols released in the air during decomposing of organic material have been associated with adverse respiratory health events. We aimed to investigate whether living in the vicinity of a large-scale composting facility is associated with adverse risks to respiratory health. Methods All large-scale composting facilities operating in England during 2005-2014 were geocoded (n=217). We estimated the distance between the population-weighted centroid of each census output area (COA) in England and the nearest composting facility. Only COAs within 4km of a composting facility were considered, excluding any COAs lying within 4km of more than one composting facility. Hospital admissions with a primary diagnosis of any respiratory condition (ICD-10: J00-J99), respiratory infections (ICD-10: J00-J22), asthma (ICD-10: J45-J46), COPD (ICD-10: J40-J44), and cystic fibrosis (ICD-10: E84), and whose residential postcode at time of admission fell within a study COA were analysed. We fitted a hierarchical Poisson regression model to assess association with hospital admission risk and distance to the nearest composting facility (continuous and quartiles), as proxy of exposure. We included a random intercept for each COA nested within a random slope for each composting facility to account for over-dispersion. Analyses were conducted combined and separately for each disease. Results We identified 17,489 COAs and a total of 475,849 unique hospital admissions with a primary diagnosis of a respiratory disease. We did not find any substantial increase in hospital admission risk by proximity to a composting facility for any of the diseases studied in any of the distance measures. Conclusion This national study does not provide consistent evidence of increased risk of respiratory hospital admissions in the vicinities of large-scale composting facilities. However, bio-aerosols have complex dispersion patterns thus, improved exposure assessment is required to inform policy.

## **P02.2030. Use of Integrated Urban Models to Assess Urban Sustainability and Health Impacts of Future Growth Policies in Canadian Cities**

**Abstract:** Background/Objectives: Public health and quality of life have been increasingly impacted by changes in land use and transportation. Integrated Urban Models (IUMs) support urban planning by simulating the impacts of such changes. To promote healthier cities, we need planning tools that consider sustainability and health outcomes. This study expanded the SmartPlans IUM simulation platform to produce a variety of environmental, social and economic indicators that could be used to evaluate the efficacy of alternate urban growth scenarios. SmartPlans was also expanded to evaluate the health benefits of simulated scenarios. Methods: A broad array of sustainability and health indicators was identified for incorporation in SmartPlans including 18 acute and chronic health endpoints. We obtained feedback from 128 stakeholders from academia, all levels of government organizations, and regional health authorities across Canada to support indicator selection. SmartPlans was also updated to produce concentrations of pollutants using Land Use Regression models. These concentrations, which are used in the calculations of the 18 health endpoints to evaluate health benefit outcomes, rely on the outputs of the land use and transportation modules of SmartPlans. Results: Input from stakeholders across Canada was incorporated into the final indicator selection and weighting. Simulation tests representing various land use and transportation scenarios with SmartPlans for Halifax, Nova Scotia and London, Ontario highlight the strengths of using SmartPlans to assess progress towards sustainability and health benefits. Simulations tests show the benefits of urban intensification over suburbanization. Discussion/Conclusions: This study demonstrates the utility of extending IUMs like SmartPlans to include sustainability and health indicators. SmartPlans can be used to support prioritization of environmental and health outcomes in urban decision-making and environmental planning.

## **P02.2040. Residential Proximity to Unconventional Oil and Gas Development and Air Volatile Organic Compound Concentrations in Ohio**

Elise Elliott

**Abstract:** Approximately 4 million Americans live within one mile of an unconventional oil and gas (UO&G or "fracking") well, potentially placing them in the path of toxic air emissions. We conducted a community-based, exploratory study to evaluate associations between proximity to UO&G wells and presence of volatile organic compounds (VOCs) inside and outside 66 homes (n=132 samples) in Belmont County, Ohio, an area with an active UO&G industry. Well locations were obtained from the Ohio Department of Natural Resources. Passive charcoal badges were selected as low-cost samplers that could readily be deployed both indoors and outdoors over a one-week period. Samplers were used to collect indoor and outdoor air samples over approximately nine days and were analyzed for three VOCs using gas chromatography and flame ionization detection. Using multivariate logistic regression, we assessed relationships between inverse-distance-squared-weighted (ID2W) well counts and detection rates of benzene, ethylbenzene, and toluene. VOCs were generally not detectable in the outdoor air samples (detection rate  $\leq 3\%$ ); indoor detection rates were 23% for benzene, 14% for ethylbenzene, and 49% for toluene. Three homes had indoor and one home had outdoor benzene concentrations exceeding health-based references. No associations between ID2W well count and detection rates of benzene, ethylbenzene, and toluene in residential air samples were observed. Though we had a large proportion of samples below the detection limit and did not observe any correlations, this study is among the first to compare UO&G proximity metrics with indoor and outdoor home measurements of air pollutants. Use of more sensitive sampling methods are needed for future efforts. The inclusion of additional attributes of UO&G wells and local meteorological and topographical data into proximity models could provide further insights into the potential for increased residential exposures to VOCs in communities with UO&G operations.

**P02.2050. A Six Months Exposure Assessment of Ambient PM2.5 Concentration in Kampala, Uganda: Preliminary Results from the Eastern Africa Geohealth Hub**

Lynn Atuyambe

*Lynn Atuyambe<sup>1</sup>*

Abstract: Ambient air pollution remains a major public health threat. It causes morbidity and premature deaths worldwide. Annually, an estimate of 3 million deaths occurs as a result of exposure to ambient air pollutants like particulate matter, ozone, nitrogen dioxide and sulphur dioxide globally. Indoor and ambient air pollution is a major public health challenge for rural and urban areas in Uganda. More than 90% of households in Uganda depend on biomass fuel for cooking & lighting. Worse still, ambient air pollution is on the rise due to rapidly increasing use of vehicles, congestion, dirty fuels, industrial development-steel and rolling mills, cement factories, the recycling industry, and incinerators. We measured Ambient PM2.5 Concentration using the Beta Attenuation monitor (BAM) 1022, centrally installed in the Central Sub City of Kampala Capital City Authority, Makerere University School of Public Health roof top at height of 15 metres above the ground level. The BAM 1022 generates real time data for PM2.5, Relative Humidity, Ambient Temperature, and Barometric pressure. Data analysis was done using MS Excel 2016 to generate monthly mean PM2.5 concentrations for period sept 2017-Feb 2018. Our results showed the monthly average PM2.5 concentrations for the six months was 47 µg/m<sup>3</sup>. The lowest and highest monthly mean PM2.5 concentrations appeared in Oct 2017 (36.5 µg/m<sup>3</sup>) and Jan 2018 (69.2 µg/m<sup>3</sup>) respectively. There is notable rise in monthly mean PM2.5 concentrations from Dec 2017 (50.0 µg/m<sup>3</sup>), Jan 2018 (69.2 µg/m<sup>3</sup>) through Feb 2018 (54.3 µg/m<sup>3</sup>) There is observed increase in ambient air pollution levels. These results provide a genesis of findings for generating scientific evidence on air pollution exposure in Uganda. Besides, they will give long-term assessment needed to characterize air pollution levels for all seasons, related public health impacts, and influence policy.

**P02.2060. Effect of Ambient Air Pollution on Respiratory Health of Market Women at Agbogbloshie Food Market, Situated near a Large E-Waste Recycling Site in Accra, Ghana**

John Arko-Mensah

*Joyce Enyonam Nafrah<sup>1</sup>, Twum Yaw Barima<sup>1</sup>, Emmanuel Acquah Baiden<sup>1</sup>, Julius Fobil<sup>1</sup>, John Arko-Mensah<sup>1</sup>*

*1. Biological, Environmental & Occupational Health Sciences (BEOHS), School of Public Health, University of Ghana, Accra, Ghana.*

**Abstract:** Background: E-waste recycling activities and vehicular traffic can both release a mixture of pollutants such as heavy metals dust, persistent organic pollutants (PCBs and dioxins), carbon dioxide (CO<sub>2</sub>), carbon monoxide (CO) etc. into the ambient air, exposure of which could lead to a variety of adverse health effects including respiratory health. No study has looked at the respiratory health of market women at the Agbogbloshie market. Objectives: The aim of this study was to assess the effect of ambient air pollution on respiratory health of market women at the Agbogbloshie open food market, near the infamous e-waste recycling site. Methods: This cross-sectional study utilized cluster random sampling to recruit 45 market women, aged 45-81 years, after ethical approval had been sought from the Ministry of Health. Respiratory symptoms (self-reported) data was collected using a structured questionnaire, and lung function test done by spirometry to obtain indices Forced Vital Capacity (FVC), Forced Expiratory Volume in the first second (FEV<sub>1</sub>) and FEV<sub>1</sub>/FVC. Hourly average measurements of PM<sub>10</sub>, PM<sub>2.5</sub> and CO<sub>2</sub> were taken using Met One Aerocet Comet 860 and Hobo CO<sub>2</sub> monitor respectively. Multiple regression analysis was used to test for association between pulmonary function indices, respiratory symptoms and alcohol use. Results: Respiratory symptoms were high among market women. Multivariate analysis of covariates showed the ff; increase in the frequency of wheezing and difficulty in breathing resulted in 0.081 (8.1%) and 0.133 (13.3%) reduction in lung function, (p=0.020), (p=0.024) respectively. Traders who were alcohol users had 0.122 (12.2%) reduction in lung function (adjusted). Daily PM<sub>10</sub>, PM<sub>2.5</sub> and CO<sub>2</sub> ranges were (492.41-1690.62), (72.09-168.84 µg/m<sup>3</sup>) and (3053.33-3635.22 ppm) respectively. Conclusion: Agbogbloshie market women have high prevalence of respiratory symptoms such as cough, colds, sore throat and repeated sneezing, and reduced pulmonary function indices.

## P02. Global Health, Environmental Health Disparities and Other Social Issues 2

### **P02.2070. Residential Segregation and Transportation-Related Air Pollution Exposure Disparities in United States Urban Areas, 2000-2010**

Lara Clark

*Lara P. Clark<sup>1</sup>, Shounak Bose<sup>1</sup>, Dylan B. Millet<sup>2</sup>, Julian Marshall<sup>1</sup>*

*1. University of Washington, Seattle, WA, United States.*

*2. University of Minnesota, St. Paul, MN, United States.*

**Abstract:** Background: Residential segregation has been proposed as a factor contributing to environmental health disparities by race-ethnicity in the United States (US). This study investigates relationships between residential segregation and transportation-related air pollution (TRAP) exposure disparities across US urban areas and over time. Methods: We combined estimates of a TRAP (nitrogen dioxide [NO<sub>2</sub>] annual average concentrations from a national regression model) with Census demographic data for urban areas in the contiguous United States (n= 481) in 2000 and 2010. We estimated two aspects of differences between race-ethnicity minorities and non-Hispanic whites: disparities in NO<sub>2</sub> air pollution exposure and segregation in residential location (dissimilarity index). We constructed linear regression models relating those two aspects (racial disparities in exposure; residential racial segregation), controlling for racial disparities in urbanicity, racial economic disparities, racial diversity, population, pollution, and region. Results: After controlling for other urban characteristics, residential segregation is positively associated (p<0.001) with racial disparity in NO<sub>2</sub> exposure in 2000 and in 2010, and change in residential segregation over time is positively associated (p<0.001) with change in racial disparity in NO<sub>2</sub> exposure (adjusted R<sup>2</sup>: 0.65 [2000], 0.66 [2010], 0.38 [change: 2000-2010]). Increasing segregation across the interquartile range (holding all other variables constant at mean value) is associated with a 30% (0.2 ppb) increase in racial disparity in NO<sub>2</sub> exposure in 2000 and a 40% (0.2 ppb) increase in 2010. Conclusions: Higher levels of racial segregation were associated with larger racial disparities in TRAP exposure in 2000 and in 2010. Larger reductions in segregation over time (2000 to 2010) were associated with larger reductions in racial disparities in TRAP exposure.

## **P02.2080. Household Air Pollution and Glycated Hemoglobin among Women in Honduras: Baseline Data from Two Seasons**

**Abstract:** **OBJECTIVE:** Growing evidence suggests a link between air pollution and cardiometabolic diseases, such as diabetes, yet most data come from ambient air pollution studies. We evaluated the exposure-response associations between household air pollution from traditional, wood-burning cookstoves and glycated hemoglobin (HbA1c), an estimate of average blood glucose concentration over the past 3 months, among women in rural Honduras. **METHODS:** We assessed two time points at baseline (rainy and dry seasons) from an ongoing randomized trial among 231 women, for a total of 462 observations. Exposure to household air pollution included 24-hour gravimetric personal and kitchen fine particulate matter (PM<sub>2.5</sub>) concentrations. HbA1c was measured with the A1cNow+ kit. We used mixed-effects regression models adjusting for known risk factors, including age, household material wealth, physical activity, body mass index, and daily consumption of cereals (corn, grains, rice, and chip products), as well as season. **RESULTS:** Median 24-hour PM<sub>2.5</sub> concentrations were 83 (25th percentile: 51; 75th percentile: 141) µg/m<sup>3</sup> and 197 (25th percentile: 81; 75th percentile: 473) µg/m<sup>3</sup> for personal and kitchen measurements, respectively. Mean HbA1c estimates were the same for both seasons at 5.5% (Phase 1 standard deviation: 0.6, Phase 2 standard deviation: 0.7). After adjusting for relevant confounders, results were consistent with a null association. Season did not impact the effect estimates. **CONCLUSIONS:** While exposure to household air pollution has known detrimental health effects, our baseline cross-sectional results did not suggest an association with HbA1c; these results are inconsistent with limited evidence from ambient air pollution. The ongoing trial will evaluate household air pollution and cardiometabolic disease following a cleaner-burning cookstove intervention among the study population.

**Abstract:** Background: The Household Air Pollution Intervention Network (HAPIN) trial is a multi-country effort to demonstrate effects of a LPG (liquefied petroleum gas) intervention on birthweight, child health and adult chronic disease. We provide results from pilot exposure assessments at the trial site in India. Methods: We assessed 48-hr personal fine particulate matter (PM<sub>2.5</sub>) concentrations and exposures in the two candidate districts (Villupuram and Nagapattinam) in Tamil Nadu, India. Using Enhanced Children's MicroPEM (ECM) monitors we measured (i) personal exposures of the primary cook (n=40) and an older adult women (n=40), as well as kitchen concentrations, in biomass or LPG using homes (with the two groups of women drawn from different sets of households) and (ii) reductions in personal exposures and kitchen concentrations among previously biomass-using pregnant women (n=40), following the provision of LPG fuel and stoves. Results: The mean 48-hour kitchen PM<sub>2.5</sub> concentrations were 374 ± 211 µg/m<sup>3</sup> in biomass-using homes (n=33), when compared to 82 ± 81 µg/m<sup>3</sup> in LPG using homes (n=27). The personal exposures were lower than kitchen concentrations but higher in biomass using homes (121 ± 167 µg/m<sup>3</sup>) when compared to LPG using homes (82 ± 34 µg/m<sup>3</sup>). Paired measurements, performed before and after the LPG intervention among previously biomass-using pregnant women, showed a sustained reduction of 93% in mean kitchen PM<sub>2.5</sub> concentrations (from 309 ± 279 µg/m<sup>3</sup> to 29 ± 12 µg/m<sup>3</sup>) and 78% in mean personal PM<sub>2.5</sub> exposures (from 140 ± 187 µg/m<sup>3</sup> to 30 ± 28 µg/m<sup>3</sup>). Post-intervention levels were consistently less than the World Health Organization (WHO) Interim-1 Target PM<sub>2.5</sub> Guideline (35 µg/m<sup>3</sup>). Outdoor concentrations indicated limited contributions from other ambient sources. Conclusions: The overall exposure contrast at the India site of the HAPIN trial is likely to be in the steepest part of known exposure-response relationships for multiple health endpoints and argues favorably for site and intervention selection.

## **P02.2100. Analysis of PM2.5 Exposure Trends in Indian State Capitals between 2015-16 - an Environmental Justice and Equity Perspective**

Bhargav Krishna

*Bhargav Krishna<sup>1</sup>, Kishore K. Madhipatla<sup>1</sup>*

*1. Centre for Environmental Health, Public Health Foundation of India, New Delhi, India.*

**Abstract:** Introduction: Exposure to high levels of ambient particulate matter is a key risk factor for ill health in India with the Global burden of Disease ranking it the 3rd largest contributor to DALYs in 2016. Regulatory-grade monitoring, remains scarce outside a handful of major metropolitan centres, and this contributes to poor awareness of the scale and geography of the problem, and hampers documentation of health effects. It also contributes to a Delhi-centric approach to air pollution problem-solving, to the detriment of other parts of the country where exposure could be higher. Methods: We collected regulatory data on PM2.5 published by the Central Pollution Control Board for the years 2015-16 for all Indian State capitals. Annual and seasonal average PM2.5 was calculated for each city and region (South, West, Central, Indo-Gangetic Plain, and East). For periods where direct PM2.5 measurements were unavailable, station-specific or city-specific PM2.5/PM10 ratios were used to derive PM2.5 data. We also documented the number of stations per city and the data availability by station for all these state capitals. Results: Only one state capital (Aizawl) met WHO guidelines for annual average exposure, with 8 others meeting the more relaxed National Ambient Air Quality Standards. The central region registered the highest average PM2.5 levels, with little variation across seasons, compared with the IGP or other regions which exhibited strong seasonal variations in PM2.5 levels. The eastern region showed the lowest PM2.5 levels. Monitoring capacity and data availability across cities and regions varied greatly from. Conclusions: The Central Indian region has the highest exposure to ambient air pollution. In spite of it being a hub for the mining, power and steel industries, monitoring capacity in this region is scarce. Consequently, there is little discussion about the potential health impacts here. We believe this represents an environmental justice and equity issue.

## **P02.2120. Exploring Barriers and Practical Solutions for the Uptake and Use of Clean Cooking through Photovoice Methods: The LPG Adoption in Cameroon Evaluation (LACE) Studies**

Daniel Pope

*Sara Ronzi<sup>1</sup>, Elisa Puzzolo<sup>2</sup>, Lirije Hyseni<sup>1</sup>, James Higgerson<sup>1</sup>, Debbi Stanistreet<sup>1</sup>, Rachel M. Anderson de Cuevas<sup>1</sup>, Bertrand Hugo Mbatchou Ngahane<sup>3</sup>, Nigel Bruce<sup>1</sup>, Daniel Pope<sup>1</sup>*

- 1. Public Health and Policy, University of Liverpool, Liverpool, United Kingdom.*
- 2. The Global LPG Partnership, New York, United States Minor Outlying Islands.*
- 3. Douala General Hospital, Douala, Cameroon.*

**Abstract:** Background: Each year up to 4 million people die prematurely from household air pollution due to domestic use of solid fuel, mainly in low and middle-income countries (LMICs). Liquefied Petroleum Gas (LPG) is an affordable, scalable, and widely available clean fuel that provides health and environmental benefits when used for household energy in LMICs. In Cameroon, where 70% of people rely on biomass for cooking, the Government aims to increase LPG use from < 20% to 58% by 2035. Few qualitative studies have explored households' perceptions of factors affecting LPG uptake. We conducted community-based participatory research using photovoice methods to explore factors influencing LPG uptake and sustained use in South-West Cameroon. Methods: Two groups of participants from rural (n=7) and peri-urban (n=8) areas photographed aspects of their lives which prevented/enabled LPG uptake in their communities. Individual interviews (n=15) and group discussions (n=5) explored participants' reflections on the issues photographed. We conducted thematic analysis using NVivo 10 software. Results: Main barriers included difficulty in affording the initial LPG equipment and ongoing refills, scarcity of LPG retail shops and safety concerns. Key enablers/solutions included (i) increasing awareness of the benefits of LPG, (ii) additional retail shops, (iii) addressing safety concerns, (iv) repairing roads to improve distribution, and (v) reducing the refill price. We organised an exhibition of participants' photos to generate discussions between participants and representatives from government, communities, industry and media about how to assist communities with fuel transition. Conclusions: Photovoice was found to be an effective participatory approach that (i) identified factors affecting uptake and use of LPG, which could be transferable to Sub-Saharan contexts, and (ii) engaged with participants and key stakeholders to identify how to advance equitable access to LPG in Cameroon.

**P02.2130. Characterizing Ambient Air Pollution Exposures, and the Biological Mechanisms Mediating the Associated Health Effects among Street Vendors in Accra (Biommaps Study): A Study Protocol**

A. Kofi Amegah

A. Kofi Amegah<sup>1</sup>, Desmond O. Acheampong<sup>1</sup>, Alex Egyir-Yawson<sup>2</sup>

1. Biomedical Sciences, University of Cape Coast, Cape Coast, Ghana.

2. Forensic Sciences, University of Cape Coast, Cape Coast, Ghana.

Abstract: Street vendors dominate the urban landscape of developing country cities with documented reports of high levels of air pollution (AP) exposures among these workers owing to the congested traffic in these cities. There is, however, limited evidence on the adverse health experiences of street vendors. Also, the exact biological mechanisms of respiratory and cardiovascular injury from exposure to AP have not been fully elucidated. In order to better understand the adverse health effects of AP exposure so as to tailor treatment and preventive strategies, it is important to establish the biological pathways. Genome-wide association studies have the capability of identifying novel genes and genetic polymorphisms in AP response phenotypes and consequently provide insight into the biological mechanisms underlying air pollution health effects. It is against this background that our aim is to characterize air pollution levels and the associated adverse health effects among street vendors in Accra, as well as elucidating the biological mechanisms mediating the associated adverse health effects. Longitudinal study of five-year duration will be conducted. Six hundred (600) street vendors permanently working at six traffic hotspots and 600 teachers teaching in schools in three affluent neighborhoods will be recruited and followed up every three months throughout the study period. Personal AP monitoring among 200 selected street vendors and 200 selected teachers will be undertaken once a week. Spirometric (FEV1, FVC and FEV1%), exhaled nitric oxide (eNO) and BP measurements will be taken at baseline and during each follow-up visit to assess lung function, endothelial function and onset of hypertension among the participants. Blood and sputum samples will be collected at baseline and every follow-up visit to measure levels of immunological markers of oxidative stress and inflammation, lipids, and to identify novel genes, explore polymorphisms and undertake gene expression.

**P02.2150. Indoor and Outdoor Residential Ammonia Concentrations in a Low-Income Cohort of Children with Asthma in an Area of Intensive Agricultural Production**

Anne Riederer

*Anne Riederer<sup>1</sup>, Maria I. Tchong-French<sup>1</sup>, Jennifer Krenz<sup>1</sup>, Elizabeth Torres<sup>2</sup>, Lisa Younglove<sup>1</sup>, Karen Jansen<sup>1</sup>, David Hardie<sup>1</sup>, Catherine Karr<sup>1</sup>*

*1. Department of Environmental and Occupational Health Sciences, University of Washington, Seattle, WA, United States.*

*2. KDNA, Yakima, WA, United States.*

Abstract: Ambient PM and NH<sub>3</sub> have been associated with measures of asthma health among children in rural Yakima Valley, Washington. Unlike PM, ammonia (NH<sub>3</sub>) has received little attention as a residential air contaminant of concern for children with asthma. We are conducting a randomized trial of a community-based asthma education program combined with home high efficiency air cleaners in 65 Yakima children (age 6-12 years) with poorly controlled asthma from nonsmoking homes located <800 m of dairy and/or crop operations. The HEPA air cleaner includes a pre-filter designed to reduce NH<sub>3</sub>. Two-week integrated NH<sub>3</sub> samples using Ogawa passive samplers are collected at baseline and follow-up from the child's sleeping area and home yard. Here we report the baseline (pre-randomization) NH<sub>3</sub> results. Geometric mean (GSD) NH<sub>3</sub> was 11.8 ug/m<sup>3</sup> (2.7 ug/m<sup>3</sup>) in the outdoor samples (n=65; max 97.6 ug/m<sup>3</sup>) and 67.5 ug/m<sup>3</sup> (1.8 ug/m<sup>3</sup>) in the bedroom samples (n=63), with 10 of these exceeding the batch-specific upper limit of quantitation. Indoor and outdoor concentrations were weakly but not statistically significantly correlated (Pearson rho=0.13, p=0.33). Indoor levels were statistically significantly (p<0.05) associated with the winter season but no other variables tested in bivariate and multivariable regression models. In a subset of children with data on NH<sub>3</sub> product use in the home, use of glass cleaner was statistically significantly associated with indoor NH<sub>3</sub> concentrations. Future work will explore the effectiveness of the HEPA cleaners at lowering indoor NH<sub>3</sub> levels in the study households.

## **P02.2160. Biomass Burning Health Effects on Brazilian Amazon Population**

Suzana Rodrigues

*Suzana D. Rodrigues<sup>1</sup>, Alfésio L. Braga<sup>1</sup>, Luiz Alberto A. Pereira<sup>1</sup>, Francisco Chiaravalloti Neto<sup>1</sup>*

*1. Universidade de São Paulo, São Paulo, Brazil.*

**Abstract:** Forest fires occur frequently in the Brazilian Amazon and they are associated with increases of diseases among inhabitants. The aim of this study is to verify the presence of spatial autocorrelation between burns and hospitalizations due to respiratory diseases in children under 5 years and the elderly over 60 years, and cardiovascular diseases in adults between 30 and 59 years and elderly in the state of Mato Grosso. We analyzed the periods from January, 2003 to December, 2010 and January, 2011 to December, 2016. Univariate and bivariate analyzes of the Local Moran were performed on the incidence of hospitalizations by age groups and fires per area (square kilometer). Thematic maps were produced with formed clusters of incidence rates, stratified by age groups and diseases, and fires separately. The univariate thematic map of the incidences, for the first period showed that the areas at greatest risk was the northwest of the state; the fires formed an arc-shaped cluster in the north of the state. The bivariate thematic map of the hospitalizations in relation to the fires also showed the same tendency for the formation of the arch. For the second period, the results showed that the incidence, when analyzed alone, tends to form clusters in the Northwest region of the state. The burnings analyzed alone had the formation of clusters concentrated in the Northeast of the state. The bivariate clusters tended to concentrate in the Northeast region. The Moran analyzes was able to capture areas that are being deforested with the use of fire and, consequently, are causing health problems to the population. This study reinforces results found in the literature on the adverse health effects due to exposure to air pollutants generated by the burning of biomass in the Amazon region.

## **P02.2170. Assessment of Traditional and LPG Stove Use on Household Air Pollution and Personal Exposures in South West Cameroon**

Dan Pope

*Dan Pope<sup>1</sup>, Ryan T. Chartier<sup>2</sup>, James Higgerson<sup>3</sup>, Lirije Hyseni<sup>1</sup>, Sara Ronzi<sup>1</sup>, Bertrand Hugo Mbatchou Ngahane<sup>4</sup>, Elisa Puzzolo<sup>5</sup>, Nigel Bruce<sup>1</sup>*

- 4. Douala General Hospital, Douala, Cameroon.*
- 5. Global LPG Partnership, New York, NY, United States.*

**Abstract:** Introduction Cameroon has begun implementation of a national liquified petroleum gas (LPG) Master Plan to increase use of LPG from <20% to 58% of the population by 2030 to address the environmental and health impacts of reliance on solid fuel for domestic energy. The LPG Adoption in Cameroon Evaluation (LACE) studies assessed the potential impacts of replacing traditional solid cooking fuel with LPG on household air pollution (HAP) and personal exposures. Methods Samples of households (exclusive wood fuel (n=61) and primary LPG fuel (n=67)) from peri-urban and rural households in South West Cameroon were identified from LACE census surveys. PM<sub>2.5</sub> was measured over a 48-hr period using the RTI MicroPEM for kitchens (n=55; n=67), women cooks (n=61; n=67) and children (n=56; n=60). Stove-use-monitoring data, demographic and health surveys, and time activity diaries were collected alongside the exposure measurements. Results Kitchen PM<sub>2.5</sub> concentrations were significantly lower in households using LPG as their primary fuel compared to those using wood (geometric mean (GM) 23.7 vs 391.5 µg/m<sup>3</sup> p<0.0005). In addition, exposures in women (GM=14.5 vs 52.3 µg/m<sup>3</sup> p<0.0005) and children (GM=11.6 vs 29.9 µg/m<sup>3</sup> p<0.0005) were significantly lower in LPG households. Exclusive use of LPG was associated with the lowest levels of PM<sub>2.5</sub> for kitchens (exclusive =18.5 vs mixed=28.7 µg/m<sup>3</sup>), women (exclusive=13.3 vs mixed=15.9 µg/m<sup>3</sup>) and children (exclusive=11.1 vs mixed=12.0 µg/m<sup>3</sup>). Conclusion We measured significant reductions in mean PM<sub>2.5</sub> kitchen concentrations and personal exposure levels in households primarily using LPG when compared to those exclusively burning wood. Mean kitchen and personal PM<sub>2.5</sub> concentrations were lower than the annual WHO interim-target 1 guideline level of 35 µg/m<sup>3</sup>. These results show that a targeted effort to promote clean fuel adoption on a national level has the potential to significantly decrease HAP exposures of the most vulnerable populations.

## **P02.2180. Vent Pipe Emissions from Storage Tanks at Gas Stations: Implications for Setback Distances**

Markus Hilpert

*Markus Hilpert<sup>2</sup>, Bernat Adria-Mora<sup>2</sup>, Ana Rule<sup>1</sup>, Tedmund Tiberi<sup>3</sup>*

*3. ARID Technologies, Inc., Wheaton, IL, United States.*

Abstract: At gas stations, fuel vapors are released to the atmosphere from storage tanks through vent pipes. Little is known about when releases occur, their magnitude, and their potential health consequences. Our goals were to quantify vent pipe releases and examine exceedance of short-term exposure limits to benzene around gas stations. At two US gas stations, we measured vent pipe flow rates and pressure in the storage tank headspace at high temporal resolution for three weeks. We modeled atmospheric benzene levels based on measured vent emission and meteorological data. For the two gas stations, average vent emission factors were 1.4 and 1.7 lb of gasoline per 1,000 gal dispensed. Modeling suggests that an 1-hour Reference Exposure Level for benzene for the general population (8 ppb) was exceeded 160 m away from the gas station. Under stable atmospheric conditions, an occupational 15-minute exposure limit for benzene (1 ppm) was exceeded 27 m downwind from the pipe due to the highest observed 15-minute vent release (6.6 kg of gasoline). Vent emission factors are more than 10 times higher than estimates used to derive setback distances for gas stations. Setback distances should be revisited and account for temporal variability in vent emissions.

**P02.2200. A Health Evaluation of Targeted Home Energy Efficiency Upgrades for Disadvantaged Residents in Dublin, Ireland.**

Paul Wilkinson

*Emma Hutchinson<sup>1</sup>, James Milner<sup>1</sup>, Ian Hamilton<sup>2</sup>, Paul Wilkinson<sup>1</sup>*

*1. Public Health Policy, London School of Hygiene and Tropical Medicine, London, United Kingdom.*

*2. UCL Energy Institute, University College London, London, United Kingdom.*

**Abstract:** Background: There are numerous pathways by which home energy efficiency improvements may affect health. We are evaluating the Dublin "Warmth and Wellbeing" pilot scheme which is aimed at improving health, wellbeing and social inclusion through home energy efficiency improvements for people aged 55 and over living in fuel poverty and suffering from chronic respiratory disease. Methods: The evaluation has a controlled 'stepped-wedge' design in which homes of eligible participants receive energy efficiency upgrades at staggered intervals from April 2016 to March 2019. Participants are followed to the end of 2019. Principal outcome measures (measured before and after intervention) include: self-reported health and well-being scores (based on SF36, SGRQ, EQ-5D questionnaires); monitored changes in internal temperatures and indoor air pollutants; consultations and hospital admissions for exacerbations of respiratory illness; and prescription data for drugs used in the management of chronic airflow limitation (CAL) obtained from the Primary Care Reimbursement Service (PCRS). Results: To date (March 2018), 400 households of the target 1000 participants have been recruited, approximately half of whom have received energy efficiency upgrades based on healthcare worker assessment of their health and wellbeing needs. Initial analyses of baseline and post-intervention questionnaire data and month-by-month prescriptions data (for drugs under the Anatomical Classification System code R (CAL) and code J (antibiotics)) are in progress. Early indications suggest that required energy efficiency upgrades were much more substantial than originally expected. Conclusions: The Dublin Warmth and Wellbeing scheme is succeeding in implementing targeted home energy efficiency improvements for patients with chronic lung disease. The evaluation of this pilot will inform the possible expansion of the scheme in Ireland, and will be relevant to other similar settings.

## **P02.2210. Refresh the Air for Children Breath: Community Cooking Center is a Paramount Necessity among Climate Refugees in Dhaka**

Kabirul Ahsan Mollah

*Neelima A. Molla<sup>1</sup>*

*1. Bangladesh Council of Scientific and Industrial Research, Dhaka, Bangladesh.*

**Abstract:** Climate change is obvious and it will continue to change as a consequence of natural phenomena. Unlikely, geographical setting more frequent water-related climatic hazards (floods, cyclones) forced Bangladeshi poor's to become climate refugees and move to densely-populated-polluted city Dhaka. Keeping in view this problem statement, we compared and assessed different slum communities for Disability Adjusted Life Years (DALYs) lost due to asthma attack among children <5. Moreover, we also studied seasonal variations within these communities. According to pre-selection criteria one non-climate refugee and three climate refugee communities were selected by using different scientific & social techniques. A multifactor socio-epidemiological and environmental (SEE) approach was used to in-depth understand and assessed the effects of risk factors on children health. Household indoor air pollution (IAP) is one of the potential determinants to identify the impact on child health (i.e. asthma) and it is intrinsically linked with poverty. Biomass is the largest source of IAP in poor societies. Some of air quality parameters (CO, NO<sub>2</sub>, Dust-particle) were measured onsite and during each visit, asthma attack along-with breathability level were determined. The results showed that there is great difference between DALYs lost belonging climate refugee communities. Moreover, among climate refugees, mixed refugee community was the most vulnerable, showed DALYs loss of 70%. Besides, DALYs lost due to asthma demonstrated huge changes with odds ratio ranges of 3.4–5.8 in three consecutive seasons. The non-climate refugee community showed reasonably less in DALYs loss. Influencing factors, such as urban services, maternal illiteracy, fuel use, ventilation system and behaviors, strongly attenuated DALYs. Therefore, this study directed a strong link between community cooking center and increased child breathability in slums and highly recommended for policy makers in priority set up.

## **P02.2220. Neighborhood Socioeconomic Factors and Cardiovascular Disease: A Cluster Analysis in North Carolina**

Anne Weaver

*Anne M. Weaver<sup>1</sup>, Laura McGuinn<sup>1</sup>, Lucas Neas<sup>1</sup>, Robert Devlin<sup>1</sup>, Radhika Dhingra<sup>1</sup>, Cavin Ward-Caviness<sup>1</sup>, Wayne Cascio<sup>1</sup>, William Kraus<sup>2</sup>, Elizabeth Hauser<sup>2</sup>, David Diaz-Sanchez<sup>1</sup>*

*1. National Health and Environmental Effects Research Laboratory, US Environmental Protection Agency, Research Triangle Park, NC, United States.*

*2. Duke Molecular Physiology Institute, Duke University School of Medicine, Durham, NC, United States.*

Abstract: Where we live contributes to how long and how well we live. Neighborhood-level socioeconomic status (SES) is associated with health outcomes, including cardiovascular disease (CVD) and diabetes, but these associations are rarely studied across large, diverse populations. We used Ward's Hierarchical clustering to define eight neighborhood SES clusters across North Carolina (NC) using 11 Census variables, including indicators of education, race, wealth, and urbanicity. Then, we assigned 6992 cardiac catheterization patients at Duke University to neighborhood clusters. We examined the associations between cluster and coronary artery disease index >23 (CAD) at the time of the index visit as determined by coronary catheterization, hypertension, and diabetes using logistic regression adjusted for age, race, sex, body mass index, and smoking status. Four clusters were urban, three were rural, and the referent cluster was suburban. Compared to the suburban cluster, an urban cluster with low SES and a large black population had 40% increased odds of hypertension (95% CI 1.07-1.85), while the highest SES urban cluster with a small non-white population had lower odds of diabetes (OR 0.72, 95% CI 0.57, 0.92). A rural cluster with low SES and a large black population had higher odds of all outcomes (OR for diabetes 1.25, 95% CI 1.03-1.53; for hypertension 1.28, 95% CI 1.05-1.56; for CAD 1.39, 95% CI 1.15-1.69). In addition, a rural cluster with low SES and a large American Indian population had increased odds of CAD (OR 1.70, 95% CI 1.20, 2.41). We observed differences in prevalence of CVD and diabetes across NC based on neighborhood characteristics. This study has implications for future studies among diverse populations and contributes to understanding of the total environment. This abstract does not necessarily reflect EPA policy.

## **P02.2230. Environmental Pollution, Mortality Rate and Hospital Admissions in Chilean Communes, 2015**

Macarena Valdes

*Macarena Valdes<sup>1</sup>, Veronica Iglesias<sup>1</sup>, Maria P. Munoz<sup>1</sup>*

*1. Epidemiology, University of Chile. Public Health School., Santiago, Chile.*

**Abstract:** Introduction Studies have described associations between psychological, cardiovascular, respiratory, and other chronic effects and environmental exposures at the individual level. Our aim is to explore the association of different types of environmental issues and health effects as mortality rate and hospital admissions at commune level. **Methods** An ecologic study focused on the comparison of the sex-age-adjusted mortality rate and hospital admission in 139 Chilean communes, 2015. The National Survey of Socioeconomic Characterization (CASEN) provided information about the report of environmental issues such as air/ odor pollution, water pollution, solid residues and plagues of households; these data were collapsed at commune level as a prevalence. Mortality and hospital admission data were acquired from public national databases; cause-specific rates were calculated for respiratory and circulatory mortality rate, and respiratory hospital admission. Robust negative binomial regression models were run to explore the effect of each environmental prevalence on health outcomes. **Results** The total, respiratory, and circulatory mortality rate in Chile in 2015 were 5.74, 5.52, and 1.57 per 1000 individuals respectively; total and respiratory hospital admission rate were 9.25 and 0.88 per 100 individuals. The mean of report proportion about air and odor pollution, river, and natural water sources pollution, public water sources pollution, solid residues pollution and plagues was 18%, 6%, 4%, 18%, and 26% respectively. There was an association between plague prevalence and total and respiratory mortality rate. **Conclusions** Plagues prevalence was positively correlated with the total and respiratory mortality rate at commune level; the rest of environmental issues were not correlated to health outcomes. However, it needs to improve the measurement of the exposure variable at the group level.

## **P02.2250. Prevalence of and Risk Factors for Chronic Kidney Disease of Unknown Aetiology in India**

Cristina O'Callaghan-Gordo

**Abstract:** Background: Studies in central America and Sri Lanka have reported a high burden of chronic kidney disease of unknown aetiology (CKDu). It is unknown whether CKDu occurs in other regions of the world and what the risk factors are. Methods: We estimated the glomerular filtration rate (eGFR) and the prevalence of eGFR below 60ml/min per 1.73m<sup>2</sup> (eGFR<60) (a proxy definitions of CKDu) in 12,500 people without known risk factors for chronic kidney disease (diabetes or hypertension) or heavy proteinuria. Participants were enrolled in three population-based studies in urban and rural areas of Northern and Southern India between 2010-2014. Results: The mean eGFR was 105.0±17.8 ml/min per 1.73m<sup>2</sup>. The prevalence of eGFR<60 was 1.6% (95%CI=1.4-1.7), but this figure varied markedly between areas, being highest in rural areas of Southern Indian [4.8% (3.8-5.8)]. In Northern India, older age was the only risk factor associated with lower mean eGFR and eGFR<60 [regression coefficient (95%CI)=-0.94 (0.97 - 0.91); OR (95%CI)=1.10 (1.08-1.11)]. In Southern India, risk factors for lower mean eGFR and eGFR<60 were residence in a rural area [-7.78 (-8.69 - -6.86); 4.95 (2.61-9.39)], older age [-0.90 (-0.93 - -0.86); 1.06 (1.04-1.08)] and less education [-0.94 (-1.32 - -0.56); 0.67 (0.50-0.90) for each five years at school]. Conclusions: Reduced eGFR that is not associated with traditional risk factors for CKD is common in rural settings of Southern India. This is the first population-based evidence, using standardised methods, which indicates that CKDu is present in India and is not confined to central America and Sri Lanka.

## **P02.2260. Residential Built-Up Area in Relation to Markers of Cardiovascular Health in Peri-Urban South India**

Cathryn Tonne

*Margaux Sanchez<sup>1</sup>, Carles Mila<sup>1</sup>, Albert Ambros<sup>1</sup>, Otavio Ranzani<sup>1</sup>, Sanjay Kinra<sup>2</sup>, Payam Dadvand<sup>1</sup>, Cathryn Tonne<sup>1</sup>*

*1. Air pollution and Urban environment, ISGLOBAL, Barcelona Institute for Global Health, Barcelona, Spain.*

*2. Non-communicable Disease Epidemiology, London School of Hygiene and Tropical Medicine, London, United Kingdom.*

**Abstract:** Much of India is experiencing rapid urbanization in parallel with increases in non-communicable diseases, thus being an attractive setting to investigate the impact of urbanization on health. We investigated associations between contemporaneous built-up area and markers of cardiovascular health (blood pressure, fasting glucose, HDL cholesterol, and triglycerides) in the Andhra Pradesh Children and Parents Study (APCAPS) study. The study population included 5800 adults (53% male, mean age 36) living in the peri-urban area South East of Hyderabad, India. Health data were collected in 2010-2012 following standardised protocols. Three built-up indices were obtained from Landsat satellite imagery for year 2009: Impervious Surfaces, Urban Index, and Normalized Difference Built-up Index. We additionally conducted a random forest supervised classification algorithm. We derived mean exposure at residence of all 4 metrics using 100-m, 300-m, and 500-m circular buffers. We used sex-stratified mixed effects models to estimate the association between log-transformed health outcome and exposure metrics accounting for spatial clustering and confounders. The built-up metrics were strongly correlated and yielded similar results. In women, increased built-up area around residence was significantly associated with increased systolic and diastolic blood pressure (+0.8% [0.1-1.4] and +1.1% [0.3-2.0] per 6% increase in 300-m impervious surface, respectively) and increased triglycerides (+3.3% [0.9-5.8] per 7% increase in 500-m urban index). In men, corresponding associations were not significant. Residential built-up area was associated with modest increases in blood pressure and triglycerides in Indian women. On a population-scale, such increases could contribute to the increasing burden of cardiovascular diseases in India. Further work will investigate the role of potential mediators (including air pollution and lifestyle) of the observed associations.

## **P02.2270. Biomonitoring Study among People Living near Abandoned Metal Mines in Southern France**

Amandine Cochet

*Amandine Cochet<sup>1</sup>, Clémence Fillol<sup>2</sup>, Marie-Laure Bidondo<sup>2</sup>, Julie Chesneau<sup>2</sup>, Agnès Guillet<sup>2</sup>, Alain Le Tertre<sup>2</sup>, Damien Mouly<sup>3</sup>*

- 1. Regions Division , Santé publique France, Montpellier, France.*
- 2. Environmental Health Division, Santé publique France, Saint-Maurice, France.*
- 3. Regions Division, Santé publique France, Toulouse, France.*

**Abstract:** After more than 100 years of past industrial mining activity in the Gard department (Southern France), significant pollution of soils with lead, arsenic and cadmium has been observed. To better understand the exposure of neighboring populations, Santé publique France (the French Public Health Agency) conducted a population biomonitoring study. The objectives were to measure the biological exposure levels, to identify the key factors of exposure and to propose appropriate measures to reduce human exposure. The study took place in a sensitive context with significant media pressure. A cross-sectional study was conducted among the general population and participation was on a voluntary basis. Different data was collected: biological samples (blood for lead and urines for arsenic and cadmium), questionnaire on eating habits and lifestyles, environmental samples in soils and house dust. The levels of lead, arsenic and cadmium were quantified and a generalized linear model was used to determine the risk factors. Santé publique France relied on a multidisciplinary external advisor committee to translate the results into appropriate operational measures. The committee completed the process by interviewing various stakeholders (elected officials, local authorities, associations and residents' representatives). The participation rate was 23.5% (651/2774). Nearly a quarter had an over-exposure of arsenic and 13% of cadmium. Blood lead levels were not different from those observed in the French population. In addition to the expected key factors (age, sex, alcohol and tobacco consumption), biological levels were influenced by pollutant concentrations in soils and the consumption of certain local products. Pollutants in dust were not correlated with biological levels. However, the frequency of home cleaning was associated with a decrease in biological levels (lead, arsenic). Collective and individual proposals for exposure reduction were formulated.

**P02.2280. Investigation of Cadmium Exposure in Regards to Smoking Status and Moose and Caribou Organs Consumption in Northern Canada**

Brian Laird

*Mylene Ratelle<sup>1</sup>, Brian Laird<sup>1</sup>*

*1. University of Waterloo, Kitchener, ON, Canada.*

Abstract: Country food consumption among northern populations is associated with improved nutrition but occasionally can also increase contaminant exposure. Elevated cadmium levels in organs of moose harvested in the southern Mackenzie Mountains resulted in a food consumption notice by the Health and Social Services Department of the Northwest Territories, to recommend that people limit their consumption of liver and kidneys. Liver and kidneys of both moose and caribou are regularly consumed as country foods consumed in the Northwest Territories. The aim of this work is to report the levels and assess the determinants of cadmium exposures among communities of the Northwest Territories. The contaminants biomonitoring project includes dietary assessments (e.g. Food Frequency Questionnaire) and the collect of urine and blood samples. Participants were free to take part in any of the components of their choice (food questionnaires, hair/urine/blood sample). Cadmium was quantified using an inductively coupled plasma mass spectrometer (ICP-MS). The association between cadmium level, co-factors (age, sex) and potential sources (consumption of moose and caribou kidney and liver, smoking) were investigated. The 331 participants from the first 13 months of sample/data collection provided 144 blood and 127 urine samples. Participants who reported eating organs (liver, kidney) of moose and/or caribou did not have significantly higher cadmium levels. Instead, smoking status was significant determinant of cadmium levels in both blood ( $p < 0.001$ ) and urine ( $p = 0.006$ ). Results show cadmium levels similar to those observed in other populations in Canada. These results are supporting ongoing efforts to identify health priorities and plans in response to environmental monitoring data.

## **P02.2290. The Great (Cannbis) Smoke Out: Case-Only Analysis of Calls to a Canadian Poison Centre**

Tom Kosatsky

*Tom Kosatsky<sup>1</sup>*

*1. EHS, BCCDC, Vancouver, BC, Canada.*

Abstract: Each April 20 (4/20), thousands across North America celebrate cannabis use by attending public 4/20 events. Vancouver (BC, Canada) hosts around 40 000 celebrants. We assessed how callers to a poison centre on 4/20 differ from callers on other days of the year. We hypothesized that 4/20, would attract first-time or occasional cannabis users. We conducted a case-only analysis of BC Poison Centre call records from 2013-2016 to quantify the degree to which individual and situational factors modify the risk of a poison centre call about cannabis exposure on 4/20. Modifying factors considered included age, sex, cannabis formulation, caller location, and cannabis-use history. Data were extracted from poison centre records. We defined event cases as callers on 4/20 or the day after reporting cannabis exposure and comparison cases as those reporting cannabis exposures on other days of the year. Cases reporting the use of illicit substances other than cannabis were excluded. We identified 19 event and 721 comparison cases from 2013-2016. Univariate regression produced interaction odds ratios for a cannabis-exposure call on 4/20 among those with certain characteristics compared to those without. 4/20 callers were more likely to have consumed edible cannabis products than other formulations, and more often called from Vancouver itself than elsewhere in BC. Adjusting for location, the odds of being a 4/20 cannabis caller were 3.7 times higher among consumers of edible marijuana products (95% CI, 1.39-11.82). Surprisingly, 4/20 calls from first-time users or from children and teens were not more frequent. Results highlight concerns for edible cannabis products: delayed absorption contributes to users consuming successive servings of edible cannabis product while waiting for the drug's psychoactive effects to begin. 4/20 event messaging, product packaging, and health providers should warn users about the particular effects of edibles.

## **P02.2300. Ending Open Defecation: A Struggle to Evoke Behavioral Change**

Elizabeth Abba

*Elizabeth J. Abba<sup>1</sup>*

*1. Xavier School of Sustainability, Xavier University Bhubaneswar, Bhubaneswar, India.*

Abstract: Evolution of toilet, a significant chapter in the history of human civilization, is a link between life and health, society and environment. To promote Sustainable Development Goals and National Health Mission of India, eradication of Open Defecation(OD)is necessary. The present qualitative research study finds out causes which encourage and discourage people to adopt open defecation. A total of 36 households were selected from five villages in Puri district of Odisha, India. Only 30.56% of all the households studied had adopted use of toilets at homes. 27.88% did not have toilets and 41.67% were having toilets but not using them. 'Lack of funds' for construction, was reported as one of the prime reasons by 60% of households without toilets. Members of these households had no more than 5 years of education and believed that open defecation was healthier. They believed that it is inappropriate to defecate near kitchen or temple, as toilet brings bad odour and impurity. On the other hand, household members using toilets selected hygiene and women privacy as primary reasons. 73% of them fell within the education category of 'graduate' and 10-12 years of education. However, 82%, of them had toilet located outside the house for religious reasons. Hence poor economic condition, lack of knowledge, cultural practices, personal preference, poorly built GOI toilets, lack of access to water and family influence were found encourage OD. Decent income, education, awareness, women's safety, social status, privacy discouraged OD. Interviewees felt that small cramped structures of government subsidized toilets prevent their usage. Hence, we recommend latrine design, wherein toilet will be bigger than the standard, built at back of the house. It would lack a roof to allow sufficient ventilation and latrine pit will be surrounded by grass. Such a design will enable switching from the fields to the latrine pits. We also recommend Behavior Change Communication as an effective approach

## **P02.2310. Assessing the Evolution of Mortality in Spain during and after the Great Recession. a Spatio-Temporal Bayesian Multivariate Age-Period-Cohort Model**

Marc Saez

*Marc Saez<sup>1</sup>, Maria A. Barceló<sup>1</sup>, Aurelio Tobias<sup>2</sup>*

*1. Research Group on Statistics, Econometrics and Health (GRECS), University of Girona and CIBER of Epidemiology and Public Health (CIBERESP), Girona, Spain.*

*2. Instituto de Diagnóstico Ambiental y Estudios del Agua, Consejo Superior de Investigaciones Científicas (CSIC), Barcelona, Spain.*

**Abstract:** Background: Although mortality from all causes in Spain already showed a decreasing trend before the Great Recession, during this there was an even greater reduction. Right after this, however, there was a change in trend, with a significant growth in mortality. Nevertheless, that time trend observed in the period scale may not be equal to the trend in the age or in the cohort scales. Objectives: Our main objective is to use Bayesian multivariate age-period-cohort (APC) models to assess the temporal trends of mortality in the three time scales and stratifying by sex, profession and region of residence of the deceased, in Spain in the period 1998-2014. Our second objective is to extend the Bayesian APC model in order to detect spatial clusters at the level of small areas. Methods: We have all the deaths occurred in Spanish cities of 20,000 inhabitants or more between 1998 and 2014 in each of the census tracks of the municipalities. We use Bayesian multivariate APC, stratifying by sex, profession and region of residence of the deceased. We include correlated overdispersion parameters and correlated smoothing priors, both across those strata. In addition, we extend the model to incorporate spatio-temporal heterogeneity in small area (census tracts) rates. Inference is made through the integrated nested Laplace approximation (INLA). Results: Our preliminary results show that time trends in all-cause mortality differ in the three scales (age, period, cohort). Temporal trends in the period scale differ for sex, with a decrease in the age-specific mortality rate from 2014 onwards in women and a significant increase in men. However, this growth only occurs in more precarious groups such as the unemployed, workers in the primary sector and unskilled workers. Conclusion: It is important to use APC models that capture significant cohort-based experiences and to take into account similar variables that act on the different time dimensions.

## **P02.2330. Identification of Vulnerable Communities with High Lead Exposures Residing in Michigan**

Jianping Xue

*Jianping Xue<sup>1</sup>, Valerie Zartarian<sup>2</sup>, Antonios Poulakos<sup>1</sup>, Lindsay Stanek<sup>1</sup>*

- 1. US EPA, RTP, NC, United States.*
- 2. US EPA, Boston, MA, United States.*

Abstract: Lead exposure is associated with numerous harmful effects in children and adults, including adverse neurological, cardiovascular, kidney, developmental, and reproductive outcomes. Exposure to even small amounts of lead can be harmful to a child's developing brain, resulting in detrimental effects on IQ and behavior. Over the past 50 years, lead exposure for the US population has decreased, resulting in lowered blood lead levels. However, there are still likely to be vulnerable communities (i.e., those overburdened with few resources and disproportionately impacted by lead exposures) where significant sources of lead remain that need to be identified to prevent public health crises like those observed in Flint, Michigan and East Chicago, Illinois and Indiana. We obtained a blood lead dataset from the state of Michigan comprised of measurements from young children (average age ~7 years old) collected over 10 years totaling ~2.5 million data points. Each individual blood lead measurement was geocoded to determine if neighborhood clusters existed with high lead exposures. We used ARCMAP 10.3.1 ([Getis-Ord Gi\*] and Gluster and outlier analysis [Anselin Local Morans I]) to identify communities with high blood lead levels (hot spots) by weighing the number of people with high blood lead levels (e.g., 3.5 or 5 µg/dl) by population or total number of people for blood lead screening. Lead concentrations in air, soil, dust, and drinking water, as well as other potential contributors to lead exposure were analyzed with blood lead data, including house age, environmental justice indices, census data, and major roads with traffic information. Preliminary results showed census tract clusters with high percentages of elevated blood lead concentrations that are related to lead concentrations in soil and dust, house age, environmental justice indices and other factors. These findings are important to target highly vulnerable communities to reduce the risk of lead exposure.

## **P02.2340. Mercury Levels in Women and Children from Suriname**

Jeffrey Wickliffe

**Abstract:** Background: Small-scale, artisanal gold mining in Suriname frequently uses mercury to collect gold from sediment/soil slurries. Much of the mercury used in this process ends up in the surrounding watersheds including fish that inhabit these areas. Locally harvested fish are a staple source of protein for many communities in the interior areas of Suriname. There is concern that women and children in certain interior areas and possibly others (e.g. the capital Paramaribo) may be exposed to unacceptably high levels of mercury. Methodology: Hair samples were collected from women and children in 5 villages in the interior of Suriname. These included 3 villages within the primary gold-mining area and 2 villages upstream of the gold-mining operations. Collection and analysis of these samples was supported in part by our GEOHealth planning award. Hair samples have also been collected from women in the capital of Suriname, Paramaribo. Blood samples are also being collected from women in Paramaribo and several interior villages. Results: Women and children from the interior villages had hair mercury levels that were on average 2-2.5X (range of 1.6-5.6 µg/g) the concentration used by the USEPA as an actionable level (1.1 µg/g) considered to be of health concern. Women from Paramaribo had hair mercury levels that were on average 0.5X that of the action level used by the USEPA, however 26% still had hair mercury levels above this action level. Conclusion: Mercury in hair samples from women and children primarily in interior areas of Suriname are quite similar to those found in previous cohort studies documenting negative neurodevelopmental impacts on children that have been prenatally exposed. Additional research underway will help determine if there are any neurodevelopmental effects resulting from such exposures in these culturally diverse and unique communities in comparison to those that have been examined in previous work.

**P02.2350. Explaining Mercury Levels in Pristine and Gold Mining Impacted Aquatic Ecosystems of Suriname (South America)**

Paul Ouboter

Abstract: Since 1985 a new gold rush has hit the eastern part of Suriname. Small-scale gold miners use mercury to amalgamate the gold. An estimated 40,000-200,000 kg of mercury is released into the environment annually. Measurements of total mercury in water, bottom sediment and fish in 53 localities spread all over Suriname showed high pollution levels in gold mining areas, but also in pristine Central and Western Suriname. The average mercury level in bottom sediment surpassed the Canadian standard for sediment in most localities, except the coastal plains. Of the predatory fish, 41 % had a mercury level above the European Union standard for human consumption. Core samples in floodplains showed a higher mercury level in the layers near the surface, indicating a recent anthropogenic source. High mercury levels in pristine areas can be explained by mercury being emitted and evaporated to the atmosphere in the mining areas, transported to the south-west by the prevailing north-eastern trade winds, and partly deposited in Central and Western Suriname, especially in areas with high precipitation. We hypothesize that a second mechanism is likely to impact the biological availability of mercury in the aquatic environment: mercury is easily bound to small sediment particles. Streams in mining areas are usually very turbid as a result of the mining activities. Part of the mercury released in these streams will bind to the suspended sediment. These sediment-mercury particles are too large to pass through biological membranes and are therefore less biologically available. This mechanism does not apply to pristine streams where turbidity is usually at a lower level. This could explain the significantly higher mercury levels in predatory fish in pristine streams compared to streams in gold mining areas. Mercury pollution in Suriname is causing elevated levels in the human population, with the highest values measured thus far being registered in a village far upstream of any gold mining.

## **P02.2360. Toxic Metals Exposure Biomarkers among Children Living near Battery Recycling Industry**

Shohreh Farzan

*Shohreh F. Farzan<sup>1</sup>, Jill Johnston<sup>1</sup>*

*1. Preventive Medicine, University of Southern California, Los Angeles, CA, United States.*

**Abstract:** The last active lead-acid battery recycler located west of the Mississippi River is located in a low-income, primarily Hispanic community in eastern Los Angeles County. This secondary lead smelter processes millions of spent automotive batteries per year and community members have raised concerns about residential exposure pathways and the resulting public health threat. Battery recycling operations are notoriously associated with airborne and suspended dust releases of toxic metals, including lead (Pb), arsenic (As), cadmium (Cd), and antimony (Sb), which frequently exceed air quality standards. Initial screening of soil samples found concentrations of Pb, Cd, and As 30, 400, and 500 times higher, respectively, than California residential soil health-based standards. In collaboration with a local environmental justice organization, we developed a community-engaged study to characterize individual biomarkers of toxic metal exposures among children living in the communities adjacent (within 2.5 miles) to the smelter. Initial analyses of urine and toenail samples suggest that exposures among children may vary widely. In preliminary analysis of children's toenail samples, we detected a range of toxic metals levels, including As (Mean, SD, range= 0.28 µg/g, 0.24, 0.08-1.43); Pb (0.93 µg/g, 0.85, 0.07-3.83); Sb (0.19 µg/g, 0.19, 0.02-1.06). Using factor analysis, we observed that exposure to several metals of concern, including Pb, As, Cd, appeared to co-occur with Sb, which is thought to be a marker of secondary lead smelter emissions, suggesting that children are likely exposed multiple metals in combination. While toenails have yet to be fully characterized as a biomarker of metals exposure in relevant reference populations, these preliminary results indicate that children living near an active smelter in east Los Angeles county demonstrated variation in their exposure to combinations of metals, with some children potentially falling into exposure ranges of concern.

## **P02.2380. Heavy Metal Levels and Stunting in Healthy Ugandan Children**

Emily Moody

*3. Pediatrics, Makerere University, Kampala, Uganda.*

**Abstract:** Introduction: The industrial transition of the past decades has increased the burden of toxic pollution in many low-income countries. Children growing up in these countries now face potentially high exposures to increasingly complex mixtures of metals. Methods: We recruited 100 healthy children between 6 and 59 months old who reside in the Katanga urban settlement in Kampala, Uganda, near Mulago Hospital. After recruitment, participants were accompanied to Mulago Hospital for a physical exam, blood sample collection, and environmental questionnaire. Results: Mean age was 27.9 mos (range 6-59 mos). 53% were male. Average height-for-age z-score (HAZ) was -0.73 (sd=1.8), and 23% were stunted (HAZ more than 2 SD below the WHO growth standard mean). We measured blood levels of 13 heavy metals (antimony, arsenic (As), barium, cadmium, cesium (Cs), chromium (Cr), cobalt, copper, lead (Pb), manganese, nickel, selenium (Se), and zinc) in all participants. A multivariable linear regression model to predict HAZ included the 13 metals and was adjusted for age, sex, hemoglobin, maternal educational level, and food security. There were significant negative associations between HAZ and chromium, arsenic, and lead, and significant positive associations between HAZ and cesium and selenium. The adjusted R<sup>2</sup> was 0.229 (p<0.001). Individual effect estimates for the five metals that were significant in our model were as follows (beta, std. error, p-value): As (-3.71, 1.52, 0.018), Cr (-1.60, 0.45, 0.0007), Pb (-0.15, 0.086, 0.095), Cs (1.85, 0.83, 0.0304), Se (0.013, 0.0074, 0.077). Conclusions: We found that stunting was prevalent in Ugandan pre-school-aged children and that higher blood levels of As, Cr, and Pb were associated with lower HAZ scores. Metal remediation and further work to identify important sources are potential intervention points to improve linear growth and developmental outcomes in this population.

**P02.2390. Identifying Environmental Sources of Metal Mixtures in Bangladesh: A Pilot Study from the Health Effects of Arsenic Longitudinal Study (HEALS)**

Tiffany Sanchez

*Tiffany R. Sanchez<sup>1</sup>, Vesna Slakovich<sup>1</sup>, Alexander van Geen<sup>2</sup>, Steven Chillrud<sup>2</sup>, Olgica Balac<sup>1</sup>, Tariqul Islam<sup>3</sup>, Faruque Parvez<sup>1</sup>, Habibul Ahsan<sup>4</sup>, Joseph H. Graziano<sup>1</sup>, Ana Navas-Acien<sup>1</sup>*

- 3. Columbia University Arsenic Project Office, Dhaka, Bangladesh.*
- 4. University of Chicago, Chicago, IL, United States.*

**Abstract:** Introduction: Environmental exposure to metals is pervasive and occurs across multiple sources. The Health Effects of Arsenic Longitudinal Study (HEALS) is an ongoing prospective cohort study predominantly focused on understanding health effects associated with arsenic exposure from drinking water. The goal of this project was to measure multiple metals in urine in order to better understand potential exposure patterns and to identify common environmental sources of exposure among this rural Bangaldeshi population. Methods: In a random sample of 199 adult HEALS participants (50% female), we used principal component analysis (PCA) with varimax normalized rotations, and hierarchical cluster analysis (CA), using Ward's method with Euclidean distances, to evaluate 15 urinary metals (As, Ba, Cd, Co, Cs, Cu, Mn, Mo, Ni, Pb, Se, Sr, Tl, W, Zn) and to assess commonalities with sociodemographic characteristics and potential sources of exposure. Results: PCA and CA showed similar patterns, suggesting 6 distinct principal components (PC)/clusters: Sr-Ni-Cs/Sr-Ni-Co; Pb-Tl/Pb-Tl-Se-Cs; As-Mo-W/As-Mo-W; Ba-Mn/Ba-Mn; Cu-Zn/Cu-Zn; and Cd/Cd. There was a strong significant association between the As-Mo-W PC/cluster and water arsenic levels ( $p < 0.001$ ). The Sr-Ni-Cs/Sr-Ni-Co PC/cluster was not related to any of the sociodemographic characteristics investigated, including smoking status and occupation. The Sr-Ni-Cs was the first PC and explained 21% of the variability. The As-Mo-W was the third PC and explained 12.5% of the variability. Day laborers appeared to have the highest exposure. Conclusions: The As-Mo-W cluster supports that groundwater is an important environmental source of metals exposure. There was one cluster (Sr-Ni-Cs/Sr-Ni-Co) for which we were unable to identify a source. Based on prior evidence and the lack of association to any sociodemographic variable, this cluster may be related to air pollution but future air sampling is necessary to confirm these findings.

**P02.2400. Pesticide Knowledge, Attitude, and Practice in the Study of Asian Women, their Offspring's Development and Environmental Exposures: The Sawasdee Birth Cohort Study in Northern Thailand**

Brittney Baumert

*Brittney O. Baumert<sup>1</sup>, Tippawan Prapamoto<sup>2</sup>, Parinya Panuwet<sup>1</sup>, Melissa Smarr<sup>1</sup>, Warangkana Naksen<sup>2</sup>, P. Barry Ryan<sup>1</sup>, Panrapee Suttiwan<sup>3</sup>, Nancy Fiedler<sup>4</sup>, Dana Barr<sup>1</sup>*

Abstract: The use of pesticides for crop production has grown in developing nations, especially in Thailand. As a result, agricultural workers are exposed to higher concentrations of organophosphate and pyrethroid insecticides than other developed nations. The Study of Asian Women and Offspring's Development and Environmental Exposures (SAWASDEE) is a maternal occupational exposure study focused on analyzing maternal pesticide exposure and neurodevelopment in the children. We will enroll 300 pregnant women from the Chom Thong and Fang regions; these two regions are to be indicative of chronic and acute exposure. For this analysis, we focused on evaluating the pesticide knowledge, attitudes, and practices (KAPs) among participants. Of all individuals enrolled (N=134), 27% reported receiving training about pesticides. Significant associations were observed between an individual's knowledge of potential harm to the fetus from spraying pesticide in their homes and their educational attainment ( $p=0.006$ , Fisher's exact test) as well as the region they live in ( $p=0.03$ , Fisher's exact test). Educational attainment was also associated with overall understanding of the purpose for pesticides including whether pesticides protect people from pest-related diseases ( $p=0.039$ , Fisher's exact test). Women who had at least some high school education had the strongest attitude or perceived risk of pesticides. Individuals appeared to understand potential illnesses related to pesticide exposure but do not have a clear understanding of the idea of vulnerable populations. In analyzing the organophosphate and pyrethroid biomarker data, we will need to consider these differences. The findings of this analysis suggest the need to educate agricultural workers to mitigate risk. Furthermore, our results warrant further investigation of knowledge, attitudes, and perceived risks in the context of biomarkers of pesticide exposures.

## **P02.2410. Maternal Methylmercury Exposure through Rice Ingestion and Offspring Neurodevelopment in Rural China: A Prospective Cohort Study**

**Abstract:** Background: Dietary methylmercury intake can occur not only through fish ingestion but also through rice ingestion; however, rice does not contain the same beneficial nutrients as fish. In rural China, where rice is a staple food, associations between prenatal methylmercury exposure and offspring neurodevelopment were investigated. Methods: 398 mothers living in Daxin, China were recruited at parturition, and had a hair sample collected. Hair total mercury concentrations were measured as a proxy for methylmercury exposure. Mothers completed a semi-quantitative food frequency questionnaire, including rice and fish ingestion. Children were assessed at 12 months (n=270, 68%) and 36 months (n=197, 49%) using the Bayley Scales of Infant Development-II, yielding age-adjusted scores for the Mental Developmental Index (MDI) and Psychomotor Developmental Index (PDI). Multivariable regression was used to model log-transformed hair mercury with outcomes, adjusting for potential confounders, including fish and rice intake. Results: Among 398 mothers, 86% ingested rice daily, 43% never ate fish, and 11% ingested fish >twice/week. Maternal hair mercury averaged 0.48 mcg/g (median: 0.40 mcg/g). At 12 months, in adjusted models, a doubling in hair mercury corresponded to a 1.5-point decrease in the MDI (95% CI: -2.9, -0.03), while a doubling in hair mercury was associated with a 0.82-point decrease in the PDI (95% CI: -2.5, 0.86). At 36 months, in adjusted models, confidence intervals were wide for both MDI and PDI. A doubling in hair mercury corresponded to a 0.32-point decrease in the MDI (95% CI: -2.1, 1.5), and a 1.0-point decrease in the PDI (95% CI: -3.3, 1.3). Conclusions: For 12-month old children from rural China, prenatal methylmercury exposure was associated with statistically significant decrements in cognition; however, this association attenuated over time and was diminished and no longer statistically significant at 36 months. Funding: NIEHS R15ES022409 R21ES026412

## **P02.2420. The Organophosphate Pesticides in Meconium of Neonates Living in Agricultural Areas in Thailand**

Pornpimol Kongtip

*Pornpimol Kongtip<sup>1</sup>, Chompunut Onchoi<sup>1</sup>, Noppanun Nankongnab<sup>1</sup>, Suttinun Chantanakul<sup>1</sup>, Dusit Sujirarat<sup>2</sup>, Susan Woskie<sup>3</sup>*

Abstract: Organophosphate pesticides are commonly used in Thailand and exposure represents a major risk during pregnancy. Prenatal concentrations of maternal urinary organophosphate metabolites were associated with infant cognitive and motor development. This study measures organophosphate pesticide in 68 meconium samples of neonates delivered from mothers living in agricultural areas in Thailand. Meconium samples were collected from neonates by nurses and kept at -45°C. The meconium samples were dissolved in deionized water and extracted with acetonitrile, cleaned up with QuEChERS technique and analyzed using gas chromatography mass spectrometry (GC-MS). The recovery of 10 organophosphate pesticides were ranged from 97.2 to 101.1% with relative standard deviation of less than 4%. The detection limits of the organophosphate pesticides ranged from 0.02-0.48 µg/g. The average age of mothers was 25.7 years old; 41% graduated at primary and secondary school. Their occupations were 33.8% agriculturist, 21.2% house wife, 18.2% general employee, 9.1% own business, 17.7% other. The result found organophosphates residue in 98.8% of meconium samples; they were 38.2% dichlorvos, 32.4% omethoate, 73.5% demeton-s-methyl, 50.0% dimethoate, 44.1% tolclofos-methyl, 50.0% malathion, 32.4% chlorpyrifos and 11.8% ethion. The median(range) of organophosphate pesticides detected were 0.67( 0.6-70.3) µg/g of dichlorvos, 5.6 (2.8-10.2) µg/g of omethoate, 0.4(0.2-0.8) µg/g of demeton-s-methyl, 0.4(0.03-26.6) µg/g of dimethoate, 0.08(0.01-0.21) µg/g of tolclofos-methyl, 0.28 (0.01-1.27) µg/g of malathion, 0.09 (0.02-0.39) µg/g of Chlorpyrifos, 0.21 (0.19-0.39) µg/g of chlorpyrifos. The pirimiphos-methyl and pyrazophos were not detected. The results found many organophosphate pesticides residue in meconium of neonates which was accumulated in fetus since the third month of pregnancy. The effect of these organophosphate pesticides residue could have effects on neurodevelopment of these babies.

**P02.2430. Association between Hepatic Index and Urinary Thiodiglycolic Acid in Residents Living near to a Big Petrochemical Complex**

Chang-Chuan Chan

*Jun-Lin Chen<sup>1</sup>, Tzu-Hsuen Yuan<sup>1</sup>, Chang-Chuan Chan<sup>1</sup>*

*1. College of Public Health, National Taiwan University, Institute of Occupational Medicine and Industrial Hygiene, Taipei, Taiwan.*

Abstract: Background/Aim No.6 Naphtha Cracking Complex in Taiwan is producing vinyl chloride monomer (VCM) and polyvinyl chloride (PVC) by Ethylene dichloride (EDC), which might release trace level of VCM and EDC in the atmosphere. Both VCM and EDC can also cause liver damage and lead to liver fibrosis or cirrhosis. The study is to estimate the exposure level of VCM and EDC with urinary thiodiglycolic acid (TdGA) as biomarker to evaluate the liver damage by VCM among residents nearby this big petrochemical industry. Methods Urine and blood samples and life style questionnaire from 771 participants were collected during 2016 in Dacheng and Zhutang Townships, South Changhua, Taiwan. The TdGA level in urine samples are analyzed by LC-MSMS with the adjustment of creatinine. Subjects who takes Vitamin B complex and has hepatitis B or C virus infection would be excluded. Fibrosis-4 (FIB-4) was utilized to evaluate the liver damage by VCM and EDC. The multiple regression was conducted to assess the relationship between urinary TdGA and the non-invasive index of FIB-4. Results In Dacheng Township, the near township to the industry, subjects were with significantly higher TdGA level of 292.1 µg/g creatinine and FIB-4 of 1.55 when compared to those in subjects in Zhutang Township, the far township to the industry. In the liner regression model, it showed the urinary TdGA levels and the distance to industry of subjects were significantly associated with the FIB-4 levels after adjusting potential confounders. To further identify the liver damage by FIB-4 level higher than 1.45, the logistic regression model also showed the urinary TdGA levels and the distance to industry of subjects were significantly associated with the liver damage after adjusting potential confounders. Conclusion Subjects with increasing level of urinary TdGA and living near to the VCM/PVC factory of the petrochemical industry lead to worse liver damage.

## **P02.2440. Biomonitoring of Exposure to Great Lakes Contaminants in New York State Burmese Refugees: Cadmium, Lead, and Mercury**

Sanghamitra Savadatti

*Wan-Hsiang Hsu<sup>1</sup>, Ming Liu<sup>1</sup>, Sanghamitra S. Savadatti<sup>1</sup>, Patrick Parsons<sup>3</sup>, Christopher D. Palmer<sup>3</sup>, Amy J. Steuerwald<sup>3</sup>, Elizabeth Irvin-Barnwell<sup>2</sup>, Wendy Wattigney<sup>2</sup>, Syni-An Hwang<sup>1</sup>*

*1. Bureau of Environmental & Occupational Epidemiology, New York State Department of Health, Albany, NY, United States. 2. Agency for Toxic Substances and Disease Registry, Atlanta, GA, United States. 3. Wadsworth Center, New York State Department of Health, Albany, NY, United States.*

**Abstract:** The New York State Department of Health conducted a biomonitoring study to assess exposure to Great Lakes contaminants among susceptible populations living in western New York State. In 2013, Burmese refugee participants (n=206) aged 18 and older living in Buffalo, NY who ate fish caught from the Great Lakes Basin provided blood samples and completed a detailed questionnaire. This analysis focuses on assessing blood cadmium (Cd), lead (Pb), and mercury (Hg) concentrations among these participants and their association with local fish consumption. The geometric mean for Cd, Pb, and Hg were: 0.72 µg/L (95% CI, 0.66-0.79), 3.13 µg/dL (2.92-3.34), and 3.66 µg/L (3.36-3.98), respectively. The geometric mean for all three metals was at least twice as high as the general adult US population [Cd: 0.30 µg/L (95% CI, 0.28-0.32); Pb: 0.97 µg/dL (0.92-1.0); Hg: 0.81 µg/L (0.74-0.90)]. Multiple linear regression was used to identify important predictors related to blood Hg, Cd, and Pb concentrations. Potential predictors included demographics, lifestyle factors, and fish consumption parameters. Hg concentrations were elevated 1.4 (1.1-1.9) times in participants who reported consuming fish/shellfish within the past three days compared to those who reported no consumption in the past week. Ethnic/tribal affiliation (Burman, Karenni, Karen and "Other") was associated with blood Hg concentrations. The Karenni, who tended to consume less fish and fish paste, had significantly lower blood Hg levels. Cd and Pb levels were associated with frequent fish paste consumption and current smoking. In conclusion, consumption of locally caught fish and fish paste may result in an increase in blood levels of Cd, Pb, and Hg. Additionally, survey results identified a low awareness of local fish consumption advisories indicating an ongoing need to provide culturally sensitive fish consumption outreach and education targeted to this population.

**P02.2450. Reliability and Factor Validity of Two Screening Test (Clock and Frontal Assessment Battery [FAB]) of Neuropsychological Effects on Exposed Agricultural Workers from Maule, Chile**

Boris Lucero

*Boris A. Lucero<sup>1</sup>, Paula Ceballos<sup>1</sup>, María Teresa Muñoz-Quezada<sup>1</sup>, Carolina Reynaldos<sup>1</sup>*

*1. Faculty of Health Sciences, Universidad Catolica del Maule, Talca, Maule, Chile.*

Abstract: In recent decades, great attention has been given to the development and application of tests that evaluate the neurobehavioral and cognitive effects of exposure to neurotoxic substances such as pesticides, especially in the occupational field. Experts have stressed that it is necessary to apply tests in a context of test and re-test or health surveillance, in order to establish early monitoring in occupational populations regarding the neurotoxic effect. Thus, it is necessary to test assessment instruments that could be utilized as "screening" measures on exposed population. The purpose of this work is to evaluate two test of pen and paper (Clock and Frontal assessment Battery [FAB]) with regard to their reliability (test-retest stability) and factor validity on a preliminary sample (N=65) of agricultural workers and pesticide applicators from Maule Region of Chile. The analysis shows that there is a test re-test strong positive correlation for the Clock Test ( $\rho = 0.609$ ,  $p = 0.01$ ) and a moderate correlation for the FAB ( $\rho = 0.404$ ,  $p = 0.01$ ). The analysis of the two test altogether showed a good consistency ( $\alpha = 0.53$ ) and between the two retest a high consistency ( $\alpha = 0.83$ ). The factor analysis showed one significant component that explains 60% of the variance. The results of this preliminary work show that these simple and economy tests present strong psychometric properties for its use as screening measures with farmworkers and pesticide applicators.

## **P02.2460. Urinary Inorganic Arsenic Concentration and Attention Deficit-Hyperactivity Disorder:**

### **A Population-Based Analysis in Arica, Chile**

Maria Munoz

*Maria P. Munoz<sup>1</sup>, Paola A. Rubilar<sup>1</sup>, Macarena Valdes<sup>1</sup>, Andrea Gomez<sup>1</sup>, Marta Saavedra<sup>2</sup>, Veronica Iglesias<sup>1</sup>*

*1. Escuela de Salud Publica, Universidad de Chile, Santiago, Chile.*

*2. Secretaria Regional Ministerial de Salud de Arica y Parinacota., Arica, Chile.*

**Abstract:** Introduction: Arsenic has been identified as a risk factor for cognitive performance in children; however, the relationship with child behavior has been little studied. The aim of this study was to explore the association between arsenic concentration in urine and attention deficit-hyperactivity disorder. Methods: Data analysis of 2.538 individuals under the age of 15, users of the Environmental Health Center between 2009 to 2015. Outcome variable: Attention deficit-hyperactivity disorder deficit diagnosis obtains by nurse and/or doctor record. Exposure variable: Urinary inorganic arsenic concentration. Multiple regression models were used. Results: Complete information was obtained from 1.976 children (22% lost data). Mean age was 9 and 50.2% were women. The median of inorganic arsenic was 16.9 mg/L (p25-p75 8-27mg/L). The prevalence of attention deficit, hyperactivity and attention deficit hyperactivity disorder (ADHD) was 10%, 9% and 7% respectively. The adjusted model for age and sex revealed modest association between inorganic arsenic and attention deficit (OR: 1.009, CI95% 1.002-1.015), hyperactivity (OR: 1.009, CI95% 1.002-1.016) y ADHD (OR: 1.01, CI95% 1.002-1.018). Conclusion: Arsenic is considered as neurotoxic and the results of this exploratory analysis show an association; however, due limitation such as the method of obtains diagnoses, the lack of complete information and the absence of other co-variables, the results should be considered with prudence.

## **P02.2470. Association of Early Life Arsenic Exposure with Prehypertension in Adolescents and Young Adults in Rural Bangladesh**

Md Alfazal Khan

*Md Alfazal Khan<sup>1</sup>, Mohammad Yunus<sup>2</sup>, Meera H. Smith<sup>3</sup>, Jane Liaw<sup>3</sup>, Craig Steinmaus<sup>3</sup>, Allan Smith<sup>3</sup>*

*3. Arsenic Health Effects Research Group, University of California, Berkeley, Berkeley, CA, United States.*

**Abstract:** Background: Evidence suggests that prolonged exposure to arsenic through drinking water increases the risk of hypertension in adults. However, few studies have evaluated the impact of early life arsenic exposure on blood pressure in adolescents and young adults. This study aimed to assess the association between in-utero-and-childhood arsenic exposure and prehypertension among the participants aged 11 to 22 years. Methods: The study was conducted in rural Bangladesh, Matlab. A cohort of 200 adolescents and young adults were enrolled of which 107 had in utero and first five years exposure to water arsenic concentration over 400µg/L (exposed group) and 93 had less than 10 µg/L(unexposed group). Blood pressure was measured using a standard mercury sphygmomanometer with an appropriately sized cuff. Prehypertension in adolescents was defined as systolic blood pressure (SBP) and/or diastolic blood pressure (DBP) between the 90th and 95th percentile for age, sex and height. For the subjects 18 years and above, prehypertension was defined as SBP ranging from 120-139 mmHg and/or DBP 80-89 mmHg. Results: The overall prevalence of prehypertension was 16.5%. The high exposure group had a higher prevalence of prehypertension compared to the low exposure group (20.6% vs. 11.8%, 1-tailed p = 0.049). After adjustment for potential confounders, the prevalence odds ratio (POR) for prehypertension was 2.3 [95% Confidence Interval (CI): 0.78-7.1, 1-tailed p=0.066] in the participants exposed to arsenic >400 µg/L in their early life. The increased prevalence of prehypertension was only evident in females (POR=8.8, 95% CI: 1.05-74.1, 1-tailed p=0.023), and not in males (POR= 1.1, 95% CI: 0.26-5.1, 1-tailed p=0.433). Conclusions: Our result suggests a possible effect of early life arsenic exposure on increased risk of prehypertension in females. We plan to follow this unique cohort to see if the effect on blood pressure persists in females as they grow older.

## **P02.2491. Groundwater Arsenic and Fasting Blood Glucose in the Context of Other Groundwater Chemicals: A Cross-Sectional Study in Bangladesh**

Matthew Gribble

*Shadassa Ourshalimian<sup>5</sup>, Abu Mohd Naser Titu<sup>5</sup>, Tom Clasen<sup>5</sup>, Mahbubur Rahman<sup>2</sup>, Kazi Matin Ahmed<sup>3</sup>, Solaiman Doza<sup>2</sup>, Jennifer Stowell<sup>1</sup>, Venkat Narayan<sup>4</sup>, Mohammad Shamsudduha<sup>6</sup>, Matthew Gribble<sup>5</sup>*

**Abstract:** Goal: To evaluate the association between groundwater arsenic (As) and fasting blood glucose (FBG), in the context of other groundwater chemicals, in Bangladesh. Methods: FBG and demographics were measured among adults  $\geq 35$  years of age ( $n=6,587$ ) participating in the Bangladesh Demographic and Health Survey (BDHS) 2011. Groundwater chemicals in 3,534 well water samples were measured in the British Geological Survey (BGS) and Department of Public Health Engineering (DPHE) 1998-99 survey. In this analysis, we assigned the nearest BGS-DPHE well's chemical exposure to each BDHS participant. Survey-estimation linear regression methods were used to model log-transformed FBG, among those using groundwater as primary drinking-water source, as a function of groundwater As, adjusting for age, sex, BMI, smoking status, diabetes medication use, region, rural or urban residence, household wealth, and educational attainment. We considered interactions of As with 14 other groundwater chemicals. Results: Compared to persons exposed to groundwater As  $< 10$  mg/L, the geometric mean ratio (GMR) of FBG was 1.01 (95% confidence interval: 0.98, 1.04) for individuals exposed to groundwater As concentrations  $\geq 10$  mg/L and  $< 50$  mg/L, and was 1.01 (0.97, 1.03) for those with  $\geq 50$  mg/L water As. Low K water may have potentiated As toxicity: Among persons with low water K, the GMR of FBG for the  $\geq 10$  and  $< 50$  As range vs.  $< 10$  mg/L was 1.03 (1.00, 1.07), and for  $\geq 50$  vs.  $< 10$  mg/L was 1.06 (1.01, 1.11). Persons with low Ca and persons with low Mg also had higher GMR of FBG in the  $\geq 10$  and  $< 50$  mg/L As group vs.  $< 10$  mg/L As. However, after Bonferroni correction no associations were significant. Conclusions: We did not detect an overall association between As and FBG. This may be due to exposure misclassification. It is possible that low groundwater K, Ca, or Mg exacerbated As toxicity to detectable levels despite exposure misclassification, but these could be false positives from multiple testing.

## P02. Prenatal and Early Life Exposures and Effects 2

### **P02.2510. Alteration of Microbiome in Colostrum and Infant Health Risks from Exposure to HCHs in Mother-Infant Pairs**

Mengling Tang

*Mengling Tang<sup>1</sup>*

*1. Epidemiology and health statistics, Zhejiang University, Hangzhou, Zhejiang, China.*

Abstract: Hexachlorocyclohexane (HCHs) are a kind of persistent organic pollutants (POPs), which are persistent, bioaccumulated and endocrine-disrupting. Infants are sensitive population for POPs and easily to be affected by dietary intake of POPs and the microbes in colostrum. This study was conducted to measure the exposure levels of HCHs in colostrum of mothers living on the island facing interchange of the Yangtze River mouth and Qiantang River mouth where were highly polluted in China, evaluate the HCHs exposure risks of newborns from dietary intake of colostrum, analyze the microbial diversity in 30 selected colostrum samples, and assess the potential effects from exposure to HCH on microbial diversity in colostrum. The concentration of  $\gamma$ -HCH was the highest of three HCH components in colostrum. When compared the total daily intake (TDI) of HCHs from colostrum with reference dose (RfD) standards, 56.7% newborns exceeded  $\gamma$ -HCH standard. *Pseudomonas*, *Enterococcus*, *Acinetobacter* and *Stenotrophomonas* were predominant bacterial genus in colostrum samples. Compared with the group with low  $\gamma$ -HCH concentration, relative abundance of *pseudomonas* in the high exposure group is significantly higher. Our findings suggested that exposure to HCHs due to environmental contamination might contribute to changes of microbial diversity in colostrum and dietary intake of HCHs in colostrum has potential health risks on newborns living in this area.

## **P02.2520. Associations of Gestational and Adolescent Phthalate Exposure with Performance Measures of ADHD Behaviors in Childhood and Adolescence**

Deborah Watkins

*Deborah Watkins<sup>1</sup>, John Meeker<sup>1</sup>, Lourdes Schnaas<sup>2</sup>, Alejandra Cantoral<sup>3</sup>, Karen E. Peterson<sup>1</sup>, Martha M. Téllez-Rojo<sup>3</sup>*

*2. National Institute of Perinatology, Mexico City, Mexico.*

*3. National Institute of Public Health, Cuernavaca, Mexico.*

**Abstract:** Attention-Deficit/Hyperactivity Disorder (ADHD) prevalence has been increasing and studies suggest that exposure to endocrine disrupting chemicals such as phthalates may play a role. However, relationships between in utero phthalate exposure and long-term ADHD symptoms are uncertain. We investigated associations between phthalate levels across gestation and ADHD behaviors in childhood (n=217) and adolescence (n=200), as well cross-sectional associations in adolescence. Pregnant women provided urine samples during each trimester for phthalate measurement, and adolescents provided a urine sample at 9-18 years of age. We administered the Conners' Continuous Performance Test (CPT) when children were age 6-11 and 9-18 years. We used multiple linear regression to examine associations between gestational (geometric mean across pregnancy) or adolescent phthalate levels and CPT scores, adjusting for age, schooling (9-18 only), maternal education, and specific gravity. CPT scores for individual domains were weakly correlated between childhood and adolescence (Spearman  $r=0.08-0.38$ ;  $n=195$ ). In utero phthalate levels were not associated with childhood CPT scores. However, in utero MBzP, MCPP, and  $\Sigma$ DBP (MBP, MiBP) were associated with poorer Omissions scores in adolescence (4.2-4.7% increase in scores per interquartile range increase in exposure). In utero  $\Sigma$ DBP was also associated with higher Response Style scores, indicating a preference for accuracy over speed. Concurrent  $\Sigma$ DEHP exposure in adolescence was associated with poorer Hit Reaction Time (HRT) SD and Variability scores, while MCNP was associated with better HRT Block Change scores. Our findings suggest that in utero phthalate exposure may have long-term effects on ADHD behaviors that may not appear until adolescence, a period of substantial neurodevelopment. In addition, phthalate exposure during adolescence may also play a role in the development of ADHD behaviors.

## **P02.2540. Prenatal Exposure to Endocrine Disruptors and Markers of Metabolic Syndrome in Preschool Age: A Birth Cohort Study**

Albino Villarreal

*Albino B. Villarreal<sup>1</sup>, Daniela Gutierrez Torres<sup>1</sup>, Consuelo Escamilla Nuñez<sup>1</sup>, Leticia Hernandez Cadena<sup>1</sup>, Isabelle Romieu<sup>1</sup>*

*1. Salud Ambiental, Instituto Nacional de Salud Pública, Cuernavaca, Morelos, Mexico.*

**Abstract:** Background. The etiology of obesity and the metabolic syndrome (MS) is multifactorial. However, the hypothesis of environmental obesogens suggests that prenatal exposure to chemicals such as phthalates and bisphenol A (BPA) may increase weight gain and risk of developing MS due to possible alterations in fetal metabolic programming. Objective. To evaluate the association between prenatal exposure to phthalates and BPA and the increase in MS markers in preschool children from Mexico. Material and methods. A total of 205 mother-child pairs were included, all participants of a POSGRAD birth cohort study. Information was obtained on sociodemographic characteristics, obstetric and health history and maternal stress during pregnancy and for the evaluation of prenatal exposure to endocrine disruptors, measurements of 9 phthalate metabolites and concentrations of bisphenol A in samples of urine from the mother was realized.. During each postnatal follow-up visit, anthropometric measurements were taken, health information was collected, and at 4 years of age cardiometabolic risk markers were measured in the children. Multiple linear regression models were run adjusting for important confounders. Results 12.7% of the children were overweight (BMI z-score) and 26.5% and 28.4% had high glucose levels and triglycerides respectively. 11.3% had low levels of HDL cholesterol. The concentrations of 7 of the 9 metabolites of phthalates and the concentrations of BPA studied were higher. We found statistically significant associations between some metabolites of phthalates with the levels of total cholesterol, non-HDL cholesterol, LDL cholesterol and the triglycerides / LDL ratio ( $p < 0.05$ ). Conclusions The results of this study strengthen the evidence that exposure to endocrine disruptors during pregnancy increases the risk of metabolic syndrome in preschool age, a situation that may increase the risk of chronic diseases at younger ages of life.

**P02.2550. Prenatal Exposure to Manganese and Maternal Psychosocial Stress-Suppression during Pregnancy Jointly Contributes to Restricted Fetal Growth**

Emilia Pawlowski

*Emilia Pawlowski<sup>1</sup>, Allison Appleton<sup>1</sup>*

*1. University at Albany, Rensselaer, NY, United States.*

**Abstract:** Introduction Metals exposure and psychosocial stress during pregnancy can contribute to poor birth outcomes. Recent work has shown early life exposure to metals and psychosocial factors jointly contribute to child growth and development. It is unknown whether prenatal metals and psychosocial stress would similarly interact and jointly affect birth outcomes. This study fills this gap and tests whether manganese exposure and maternal stress-suppression during pregnancy would synergistically affect infant birth outcomes. Methods Data were collected from the Albany Infant and Mother Study, an ongoing birth cohort. Manganese exposure was assessed in 150 subjects via toenail sample collected late in pregnancy. Maternal stress-suppression was assessed via a gold-standard questionnaire during pregnancy. Birthweight, head circumference, and infant cephalization indices ((head circumference/birthweight)\*100) were gathered from medical records and examined as outcomes. Multivariable regression models tested main effects and interaction between suppression and manganese in relation to infant birth size outcomes, adjusting for demographic, maternal health, delivery, and infant factors. Results A significant interaction between manganese and stress-suppression was observed in relation to infant cephalization ( $\beta=0.02$ ,  $SE=0.01$ ,  $p<0.05$ ), indicating that infants whose mothers had high levels of manganese and high levels of suppression experienced more asymmetric fetal growth than other groups. Interaction effects were not observed for birthweight or head circumference. Discussion the combined effect of stress-suppression and high manganese exposure during pregnancy contributed to asymmetric intrauterine growth restriction among offspring, indicating potential brain sparing during fetal development. This synergistic effect exceeds that of the main effects of each factor. Interventions designed to promote healthy birth outcomes should consider both metals and psychosocial factors.

## **P02.2560. Effect of Prenatal Exposure to Perfluoroalkyl Substances (PFASs) on Childhood Infectious Diseases up to 7 Years of Age: The Hokkaido Study**

Yu Ait Bamai

*Yu Ait Bamai<sup>1</sup>, Atsuko Araki<sup>1</sup>, Emiko Okada<sup>2</sup>, Ikuko Kashino<sup>1</sup>, Chihiro Miyashita<sup>1</sup>, Houman Goudarzi<sup>1</sup>, Hideyuki Matsuura<sup>3</sup>, Reiko Kishi<sup>1</sup>*

- 3. Research Faculty of Agriculture, Laboratory of Natural Products Chemistry, Hokkaido University, Sapporo, Japan.*

**Abstract:** Background/Aim: Perfluoroalkyl substances (PFASs) are persistent industrial chemicals that have possible effects on the immune system. We have reported the possible impact up to 4 years of age, however, effects on childhood infectious disease at later age is still unclear. We aimed to investigate the association between prenatal PFASs exposure and infectious diseases up to 7 years. Methods: A total of 2689 mother-child pairs, who were enrolled in the Hokkaido Study, were included in this data analysis. Eleven PFASs in 3rd trimester plasma were measured using UPLC-MSMS. Doctor diagnosis of otitis media, chicken pox, pneumonia, and respiratory syncytial virus (RSV), up to 7 years were extracted from the mother-reported questionnaires at 2, 4, 7 years of age. The odds ratio (OR) of log[e] transformed PFASs levels, as well as categorical values were calculated by logistic regression models adjusted for potential confounders such as infant sex, maternal age at delivery, gestational week, parity, household income, any allergies at 7y, and duration nursing. Results: Prevalence of otitis media, chicken pox, pneumonia, and RSV were 55.7%, 61.5%, 30.6%, and 16.8%, respectively. After stratified by siblings with (n=2309) and without (n=379), the increased the adjusted ORs (95% confidential interval) of pneumonia were found with PFOS (1.60, 0.94-2.71 p-value for trend in quartile model=0.039), PFDA (1.66, 1.03-2.66, p trend=0.004), and PFDoDA (1.61, 1.04-2.49, p trend=0.624) and increased the adjusted ORs of RSV were found with PFOA (1.91, 1.07-3.42, p trend=0.005) among children without any siblings. However, any of such associations were not found among children with siblings. Conclusion: Prenatal exposure to PFASs were associated with increased risk of pneumonia and RSV up to 7 years of age only among children without any siblings, however, not among children with siblings.

## **P02.2570. Perinatal Factors and the Development of Childhood Asthma**

Jiho Lee

*Jiho Lee<sup>1</sup>, Ahra Kim<sup>2</sup>, Gina Lim<sup>3</sup>, Inbo Oh<sup>4</sup>, Yangho Kim<sup>1</sup>, Taehoon Lee<sup>5</sup>*

**Abstract:** Perinatal factors are suspected to have a significant impact on the development of asthma; however, sufficiently powered studies have not been performed to investigate this issue. To evaluate whether perinatal factors and other risk factors have an independent or combined effect on the development of asthma. This study involved 3,770 children (mean age 9.1 years, range 5.68-12.16 years; 51.9% boys) who were enrolled in the Elementary School Student Cohort (2009-2014) in Ulsan University Hospital (Ulsan, Korea). Subjects were divided into an asthma group (n = 514) and a non-asthma group (n = 3,256). Multivariate analyses showed that early life (within first week) oxygen therapy (adjusted odds ratio [aOR] 1.864, 95% confidence interval [CI] 1.156-3.004) and breastfeeding (aOR 0.763, 95% CI 0.606-0.960) were 2 significant perinatal factors influencing the development of asthma. Environmental tobacco smoke (aOR 1.634, 95% CI 1.298-2.058) and parental allergic disease (aOR 1.882, 95% CI 1.521-2.328) also were identified as risk factors. Using subgroup analyses, combined effects on asthma development were observed between perinatal factors (early life oxygen therapy and breastfeeding) and other risk factors (vicinity to major roadway [traffic-related air pollution], environmental tobacco smoke, parental allergic disease, and atopy). Early life oxygen therapy and breastfeeding were identified as 2 important perinatal factors influencing the development of asthma. Furthermore, these factors showed combined effects with other risk factors (environmental tobacco smoke, traffic-related air pollution, parental allergic disease, and atopy) on the development of asthma.

## **P02.2580. Prenatal Exposure to Environmental Pollutants and Child Development Trajectories through 7 Years**

Albino Barraza Villarreal

*Albino Barraza Villarreal<sup>1</sup>, Ines Gonzalez Casanova<sup>2</sup>, Leticia Hernandez Cadena<sup>1</sup>, Isabelle Romieu<sup>1</sup>, Usha Ramakrishnan<sup>2</sup>*

*1. Salud Ambiental, Instituto Nacional de Salud Pública, Cuernavaca, Morelos, Mexico.*

*2. Department of Global Health, Rollins School of Public Health, Emory University, Atlanta, GA, USA, Atlanta, GA, United States.*

**Abstract:** Background: Prenatal exposure to environmental pollutants such as mold, lead, pesticides, tobacco, and air pollutants has been suggested to impair cognitive development. Evidence is needed from longitudinal studies to understand their joint impact on child development across time. Objective: To study associations between exposure to indoor environmental pollutants or outdoor air pollution during pregnancy and offspring cognitive development trajectories through 7 years. Methods: We included 718 Mexican mother-child pairs. Prenatal exposure to indoor environmental pollutants (mold, ventilation, pesticides, tobacco smoke, and use of vitrified clay pots) was self-reported by the mothers and integrated into an index, or objectively measured in the case of outdoor air pollutants (nitrogen oxides, benzene, toluene, and xylene). Child global cognitive development was measured at 12, 18, 60, or 84 months. Using Latent Class Growth Analysis, we identified three developmental trajectories (positive=108, average=362, low=248). We used multinomial logistic models to test associations between environmental pollutant score (EPS) or outdoor air pollutants, and cognitive development trajectories. Results: After adjustment for sociodemographic covariates, EPS was associated with the average (OR=1.26 95%CI=1.01, 1.55) and low (OR=1.41 95%CI=1.11, 1.79) trajectories compared to positive; where a unit increase in EPS means an additional prenatal exposure. There was no association between outdoor air pollutants and cognitive development trajectories. Conclusion: Children of women who reported higher exposure to indoor environmental pollutants during pregnancy were more likely to follow worse developmental trajectories through 7 years. These results support the development and testing of interventions to reduce exposure to environmental pollutants during pregnancy and early childhood as a potential strategy to improve long-term cognitive development

## **P02.2590. Housing Characteristics, Asthma Triggers, and Asthma Outcomes: Data from the American Housing Survey**

Rachel Long

*Rachel N. Long<sup>1</sup>*

*1. Association of Schools and Programs of Public Health, Washington, DC, United States.*

Abstract: Some indoor pollutants (e.g. mold, cigarette smoke) are known asthma triggers. Physical housing characteristics may affect exposure to triggers independent of socioeconomic status (SES). This exploratory analysis used 2015 American Housing Survey data on 9,558 households in 25 U.S. metropolitan areas to study relationships among housing characteristics (air conditioning (AC), home age by decade, home type (apartment, mobile home, single-family home)), indoor asthma triggers (mold, musty odors, cigarette smoke, roaches, and rodents), SES, and asthma outcomes among household children. Associations among asthma trigger presence and housing characteristics were analyzed using multivariate logistic regression adjusted for householder race, education, and income. Homes with window AC or no AC had significantly higher odds of having mold, musty odors, rodents, and secondhand smoke infiltration (SHS) than homes with central AC regardless of home type. Apartments had significantly higher odds of having mold, musty odors, SHS, and roaches than single-family homes or mobile homes. Mold, musty odors, SHS, and roaches were significantly associated with older home age. Associations among asthma outcomes and housing characteristics were analyzed using multivariate logistic regression adjusted for householder race, education, income, and presence of triggers. Housing characteristics were not significantly associated with asthma outcomes, with or without triggers in the model. Roaches (odds ratio (OR): 1.33; 95% confidence interval (CI): 1.03-1.72) and mold (OR: 1.65; CI: 1.24-2.18) were significantly associated with asthma prevalence among household children. Musty odors were significantly associated with asthma-related emergency room visits (OR: 1.73; CI: 1.01-2.91) for the youngest child with asthma in each household. This analysis suggests that some housing characteristics are associated with a higher prevalence of asthma triggers and should be considered in future research.

**P02.2600. Differences in Characteristics and Risk Factors between Asthmatic Children with and without Atopic March: A Retrospective Cohort Study**

Ching-Chun Huang

*Ching-chun Huang<sup>1</sup>, Tung-Liang Chiang<sup>4</sup>, Pau-Chung Chen<sup>5</sup>, Shio-Jean Lin<sup>3</sup>, Hui-Ju Wen<sup>2</sup>, Yue Leon Guo<sup>2</sup>*

*3. Department of Pediatrics, Chi Mei Hospital, Tainan, Taiwan.*

*4. Institute of Health Policy and Management, National Taiwan University, Taipei, Taiwan.*

*5. Institute of Occupational Medicine and Industrial Hygiene, National Taiwan University, Taipei, Taiwan.*

**Abstract:** Background Although asthma occurrence is often preceded by atopic dermatitis (AD) in the context of atopic march, a significant number of asthmatic children do not co-occur with AD. The aim of the study is to explore the phenotypic differences between asthmatic children with and without atopic march. Methods Eligible participants were selected from the 8-year-old survey of Taiwan Birth Cohort Study, and those ever diagnosed as having asthma were enrolled as study subjects. Demographic characteristics, environmental risk factors, and allergic comorbidities including AD of the subjects were retrieved by trained interviewers. We applied logistic regression models to characterize differences between the two groups. Results A total of 1999 asthmatic children were enrolled in the study, and 455 (22.8%) of them had preceding AD. Determinants favoring AD co-occurrence included maternal history of AD (odds ratio [OR]= 2.91, 95% confidence interval [CI]: 1.82-4.64) and allergic rhinitis (OR= 1.29, 95% CI: 1.00-1.65), paternal AD history (OR= 2.45, 95% CI: 1.51-3.99), maternal postpartum depression (OR= 1.37, 95% CI: 1.07-1.75), urbanization of the residence (OR= 1.56, 95% CI: 1.24-1.95), higher education of mother (OR= 1.48, 95% CI: 1.13-1.93) and father (OR= 1.32, 95% CI: 1.01-1.72), early life food allergy (OR= 3.35, 95% CI: 2.56-4.38), and history of gastritis (OR= 1.46, 95% CI: 1.10-1.93). Nevertheless, asthmatic children with early-onset attention-deficit/hyperactivity disorder were not prone to co-occur with AD (OR= 0.23, 95% CI: 0.08-0.62). Conclusions Early identification of phenotypic determinants between asthmatic children with and without atopic march may help risk stratification and early intervention.

## **P02.2610. Investigating Children's Exposure to Recycled Tire Rubber Used in Playground Surfacing**

Eric Hooker

*Eric Hooker<sup>1</sup>, Hope Nesteruk<sup>1</sup>, Stephen Harsanyi<sup>1</sup>, Khalisa Phillips<sup>1</sup>, Sarah Garland<sup>1</sup>, Rana Balci-Sinha<sup>1</sup>*

*1. U.S. CPSC, Rockville, MD, United States.*

Abstract: CPSC is assessing the potential risks to children associated with the use of recycled tire crumb rubber in playground surfaces. Such playground surfaces are a popular option due to their low maintenance, variety of colors and designs, and potential to reduce fall-related injuries. However, parents and playground owners have expressed concerns about the chemical safety of recycled tire materials used in playground surfacing. Children can be exposed to surfacing materials by oral, dermal, and inhalation routes during typical play activities on playgrounds. The scientific literature lacks information to estimate children's exposure to tire constituents from playing on recycled tire rubber playground surfaces. CPSC is using a combination of field observations, focus groups, and a national survey of parents of young children to identify behavioral exposure factors for children on playgrounds. Examples of information sought include frequency and duration of visits to playgrounds, identification and frequency of behaviors and situations that could promote exposure, and parents' awareness of potential hazards and their strategies to reduce exposure. CPSC staff will use the survey results to develop exposure scenarios and models to identify bioavailable substances in recycled tire rubber that may pose a health hazard to children using playgrounds. Subsequent risk assessment strategies will be determined based on review of new data, including the tire crumb rubber characterization and bioavailability studies underway by EPA and CDC/ATSDR, and likely will focus on the substances of highest concern. The poster will review methods and available results of playground exposure data collection and strategies for continued research efforts. This work is that of CPSC staff and has not been reviewed or approved by, and may not necessarily represent the views of, the Commission.

## **P02.2620. Concentrations of Phthalate Metabolites in Children from Poland**

Kinga Polanska

*Kinga Polanska<sup>1</sup>, Mercè Garí<sup>2</sup>, Wojciech Hanke<sup>1</sup>, Holger M. Koch<sup>3</sup>, Claudia Pálmke<sup>3</sup>, Stephan Bose-O'Reilly<sup>2</sup>*

*3. Institute for Prevention and Occupational Medicine of the German Social Accident Insurance - Institute of the Ruhr-Universität Bochum (IPA), Bochum, Germany.*

**Abstract:** Background: Endocrine disrupting chemicals (EDCs) represent a growing public health concern. This is the case of many phthalates, a group of widely used chemicals that affect the hormonal balance in both children and adults. Furthermore, there are critical life stages in which exposures to phthalates may pose an increased risk, such as the developing foetus and the early childhood. The aim of this study was to determine urinary levels of phthalate metabolites in early school children in Poland and compare these results with those observed in other European countries. Methods The exposure to 11 phthalates was determined by measuring 21 phthalate metabolites in urine of 7-year old children from the Polish Mother and Child Cohort Study (REPRO\_PL, n=250, samples collected in 2014-2017), which is the most extensive set of phthalate metabolites ever determined for Poland. Urine sample analyses were performed using on-line high performance liquid chromatography coupled to tandem mass spectrometry (HPLC-MS/MS) using internal isotope-labelled standards. Results: The highest geometric mean concentrations were found in primary monoester metabolites of di-iso-butyl, di-n-butyl and diethyl phthalate, as follows: 75.7 µg/g for MiBP (111.4 µg/g creatinine); 53.9 µg/g for MnBP (79.6 µg/g creatinine) and 42.7 µg/g for MEP (64.4 µg/g creatinine), respectively. Conclusions: These levels are similar to those found in previous studies performed in Poland, but much higher than those from other European populations. The levels of DEHP metabolites in the present study were similar to those observed among children in comparable age from Slovakia but slightly higher than those from Czech Republic and Hungary.

**P02.2630. Impact of Bisphenol A Exposure on Adiposity Trajectory in Early Childhood:  
A Prospective Cohort Study**

Youn-Hee Lim

*Youn-Hee Lim<sup>1</sup>, Young Ah Lee<sup>2</sup>, Choong Ho Shin<sup>2</sup>, Dongwook Lee<sup>1</sup>, Bung-Nyun Kim<sup>3</sup>, Inhyang Kim<sup>4</sup>,  
Yun-Chul Hong<sup>1</sup>*

- 1. College of Medicine, Seoul National University, Seoul, Korea (the Republic of).*
- 2. Seoul National University Children's Hospital, Seoul, Korea (the Republic of).*
- 3. Seoul National University Hospital, Seoul, Korea (the Republic of).*
- 4. Seoul National University Bundang Hospital, Kyunggi, Korea (the Republic of).*

**Abstract:** Background: Exposure to bisphenol A (BPA) may impact obesity development, either in the exposed subjects or offspring. Objective: To investigate the association between prenatal and postnatal exposure to BPA and children's body mass index (BMI) as well as its trajectories, in a cohort study. Methods: We recruited pregnant women in their second trimester, between 2008 and 2011; their creatinine-adjusted urinary BPA levels were measured. In 2012-2016, we measured their children's BPA levels, at ages 2, 4, and 6 years, and assessed the BMI values, z-scores, and prevalence of overweight (n = 202). Adiposity trajectories were determined in latent class mixed models. We assessed the association between prenatal mid-term exposure to BPA and postnatal exposure, at each age, and anthropometric measurements, at a single time point, at ages 2, 4, and 6 years. The relationship between prenatal exposure to BPA and adiposity trajectory, over multiple ages, was investigated through linear regression. Results: The association of prenatal and postnatal BPA concentrations with the anthropometric measurements, at a single time point, at 2, 4, and 6 years of age, were not statistically significant after controlling for covariates. However, the adiposity trajectories, over ages 2 to 6 years, were related with prenatal BPA concentrations. A 2-fold increase in prenatal BPA level was significantly associated with increasing adiposity trajectories, in early childhood, by 39.6% (95% confidence intervals: 2.2%, 90.7%). Conclusion: Adiposity trajectory, in early childhood, was affected by prenatal BPA exposure levels. The study provides supporting evidence on the transgenerational effects of BPA on children's growth.

**P02.2640. Environmental Health and Neurodevelopment: Buiding and Using Evidence to Motivate Behavior Change to Improve Children's Health**

Suhela Kapoor

*Suhela Kapoor<sup>1</sup>, Banalata Sen<sup>2</sup>*

- 1. Environmental Health, TATA Trust & Public Health Foundation of India, New Delhi, Delhi, India.*
- 2. Independent Researcher, Delhi, India.*

**Abstract:** Objectives: Environmental exposures are known to be significant causal factors contributing to more than 28% of neuro-developmental disorders (e.g. autism, ADHD, intellectual disability) in children. One of the biggest challenges for improving child cognition outcomes is lack of early assessment and monitoring tools. Methods: Many investigators have argued that concern about children's well-being can be leveraged to motivate behavior change in communities. In this direction, we are carrying out a landscape analysis to understand the epidemiological association between environmental exposures such as indoor air pollution and chemical exposure and associated neurodevelopmental outcomes. Exposure assessment is being done using questionnaires. Neuropsychological outcomes shall be assessed using Developmental Scale for Indian Infants tool. EEG, using portable devices, shall help check for attainment of neuro-physiological milestones. All these tools will be administered by local community health workers, after appropriate training. Results: This proposal is a first of its kind of Environmental Neuro-Epidemiology study in India. The questionnaires designed as a part of this study could be used as standard assessment tools. EEG will provide objectivity to the evaluation as well as enable easy-to-scale diagnosis in low resource settings. Implementing the program through primary health care workers shall enable reliable and quick assessment of neurodevelopmental status and thus, help in prevention and management of such avoidable exposures. Conclusions: We believe our activities will trigger the community's desire for collective change, and based on their gained understanding of harmful effects of environmental pollution on their children, lead to transformative change. This prospectively could give rise to the concept of a 'Community Lab' wherein people actively participate in identifying issues that challenge their well being and find solutions to mitigate the impact.

## **P02.2650. Joint and Individual Neurotoxic Effects of Early Life Exposures to a Chemical Mixture: A Multi-Pollutant Approach Combining Ensemble Learning and G-Computation**

Youssef Oulhote

*Youssef Oulhote<sup>1</sup>, Brent Coull<sup>2</sup>, Ibon Tamayo<sup>3</sup>, Frodi Debes<sup>4</sup>, Flemming Nielsen<sup>5</sup>, Marie-Abele Bind<sup>3</sup>, Pal Weihe<sup>4</sup>, Philippe Grandjean<sup>1</sup>*

*3. Statistics, Harvard University, Cambridge, MA, United States.*

*4. Occupational Medicine and Public Health, Faroese Hospital System, Thorshavn, Faroe Islands.*

*5. Institute of Public Health, University of Southern Denmark, Odense, Denmark.*

**Abstract:** Background: The majority of studies do not simultaneously consider multiple co-occurring exposures when assessing potential neurotoxicity. Objectives: To assess associations between developmental exposure to a mixture of pollutants and children's neurodevelopment using a novel approach. Methods: Concentrations of mercury (Hg), polychlorinated biphenyls (PCBs), and perfluoroalkyl substances (PFASs) were measured in maternal and children's blood at 5 years (n=449). At 7 years, children were administered Boston Naming Test (BNT) and the Strengths and Difficulties Questionnaire (SDQ). We used the G-formula combined with the SuperLearner -an ensemble learning technique- to infer effect estimates for the mixture of chemicals and for each pollutant while mutually adjusting for all exposures and potential confounders. We also constructed exposure-response curves and assessed potential interactions. Results: Most chemicals showed a negative relationship with BNT scores. An inter quartile range (IQR) increase in prenatal Hg and perfluorooctanoic acid (PFOA) concentrations was associated with 0.2 standard deviation [SD] (95% Confidence Interval [CI]: -0.3, 0) and 0.1 (95% CI: -0.3, -0.1) lower scores in the BNT, whereas a joint IQR increase in the mixture of chemicals was associated with 0.5 SD (95% CI: -0.7, -0.3) lower scores in the BNT. Additionally, an IQR increase in prenatal perfluorooctane sulfonic acid (PFOS) and PFOA concentrations was associated with 0.15 (95% CI: 0.1, 0.2) and 0.1 SD (95% CI: 0, 0.3) higher (worse) total SDQ scores. A joint IQR increase in chemicals mixture was associated with 0.2 SD (95% CI: -0.1, 0.4) higher SDQ scores. Finally, a joint IQR increase in 5-years mixture of chemicals was associated with 0.2 SD (95% CI: 0, 0.4) higher total SDQ scores. Conclusions: Using a novel multi-pollutant approach, we confirmed previously reported associations between mercury and lower cognitive function. Additional attention should be directed towards emerging PFASs.

**P02.2660. Selenium Protection Against Methylmercury Adverse Neurodevelopmental Effects in Inuit Children from Nunavik, Northern Quebec, Canada**

Abstract: In Nunavik, prenatal methylmercury (MeHg) exposure has been related to poorer visual and neuropsychological functions and greater risk of attention problems at school age. While some marine foods present high MeHg, others are also exceptionally rich in selenium (Se). Consequently, Inuit present one of the highest blood Se concentrations in the world. High Se intake may contribute mitigating some harmful effects of MeHg, although it never has been reported for prenatal exposure. Selenoneine - a potent antioxidant - may be the key form of Se protecting against MeHg in populations living off a marine diet. The present study aims to determine whether high Se intake can mitigate neurodevelopmental MeHg effects in Inuit children, and whether selenoneine is found in this population. The Nunavik Child Development Study is a prospective mother-child cohort study enrolled at birth with children followed at 11 years old. Total Hg and Se concentrations were assessed in cord and child blood, and selenoneine, in child blood. Neuropsychological and motor functions were evaluated from direct assessment of the child, attention problems by standardized teacher report, and visual function through electrophysiological testing. Control variables were documented through medical records, maternal interviews and blood biomarkers. The modifying effects of Se status on the associations between blood Hg and outcomes were examined using regression models stratified by blood Se. For almost all neurodevelopmental outcomes related to cord MeHg, the harmful effects of prenatal MeHg were significant only in the first cord blood Se tertile group. In child blood, selenoneine represented up to 20% of total Se among those often consuming marine mammals. Marine foods are central to Inuit culture and key source of nutrients for promoting healthy pregnancies and children. Understanding selenoneine health properties will help find solutions to better promote pregnancy wellness with marine foods in the Arctic.

## **P02.2670. Early Life Phthalate Exposure and Cognition at Age 8 Years: Identifying Windows of Heightened Vulnerability**

Medina Jackson-Browne

**Abstract:** Background: Early-life phthalate exposures may adversely affect children's neurodevelopment by disrupting thyroid function, reducing gonadal hormone levels, or altering concentrations of fatty acids in the brain. We attempted to identify windows of heightened vulnerability to phthalate exposures during fetal period and early childhood. Methods: We used data from 204 mother-child pairs in the HOME Study (Cincinnati, Ohio), a longitudinal pregnancy-birth cohort. We quantified phthalate biomarkers in urine samples collected up to twice at gestational visits and up to 6 times during childhood visits at ages 1-8 years. We assessed children's intelligence (IQ) at age 8 years using the Wechsler Intelligence Scale for Children-IV. We estimated covariate-adjusted associations between log<sub>10</sub>-transformed biomarker concentrations and children's IQ at each visit, and tested for differences in these associations across visits using multiple informants models. Results: The associations between phthalate biomarker concentrations and IQ varied by visit (biomarker\*visit interaction p-values<0.2). Concentrations of monobenzyl phthalate, mono (3-carboxypropyl) phthalate, and monoethyl phthalate at ages 2 and 3 years, and di(2-ethylhexyl) phthalate (ΣDEHP) metabolites at age 3 years were inversely associated with children's full-scale IQ. For example, each 10-fold increase in urine ΣDEHP concentrations at age 3 was associated with a 4.9-point decrease in full-scale IQ (95% confidence interval [CI]: -8.8, -1.1). Concentrations of mono-n-butyl phthalate (MnBP) at age 4 years and mono-isobutyl phthalate at gestation and age 4 years were positively associated with children's IQ. For instance, each 10-fold increase in urine MnBP concentrations at age 4 years was associated with a 5.0-point increase in full-scale IQ (95% CI: 0.8, 9.2). Conclusion: In this cohort, associations of gestational and childhood urinary phthalate biomarker concentrations with IQ scores depended on the timing of exposure.

## **P02.2680. Maternal Plasma Concentrations of Per- and Polyfluoroalkyl Substances and Breastfeeding Duration in the Norwegian Mother and Child Cohort**

**Abstract:** Background: Per- and polyfluoroalkyl substances (PFASs) have been widely produced, many of them persist in the environment, and have been associated with various health effects. Previous studies have identified inverse associations between perfluorooctanoic acid (PFOA), perfluorooctane sulfonate (PFOS) and breastfeeding duration. Methods: We measured the associations between plasma concentrations of 9 different PFASs and cessation of breastfeeding before 3 and 6 complete months using women from the Norwegian Mother and Child Cohort Study (MoBa). The study population includes 1716 primarily nulliparous women from two previous studies of MoBa participants, all enrolled from 2003-2007. The association was measured using Cox proportional hazards models adjusted for confounders and study design. Results: Concentrations of PFASs in this population were lower than concentrations in the previous studies on this topic. We found associations between increasing concentrations of perfluorononanoic acid (PFNA), perfluorodecaconic acid (PFDA), perfluoroundecanoic acid (PFUnDA) and decreased breastfeeding cessation (increased duration). The strongest associations were seen between PFDA and PFUnDA and cessation before 3 months: (hazard ratio = 0.73, 95% confidence interval: 0.62, 0.86). In our population, the other PFASs appeared to be unassociated with breastfeeding cessation or slightly protective. Conclusions: This study is the largest to address this question and is the most well-situated to avoid confounding by previous breastfeeding, given our high proportion of nulliparas. The identification of positive associations between previously unexamined PFASs concentrations and breastfeeding duration is novel and may be explained by differences in transplacental transfer rates.

## **P02.2690. Childhood Lead Exposure and Anthropometry through Adolescence in Girls**

**Abstract:** Cross-sectional studies suggest that postnatal blood lead concentrations (PbB) are negatively associated with child growth. Few studies prospectively examined this association in populations with low PbB. We investigated longitudinal associations of childhood PbB and subsequent anthropometric measurements in a multi-ethnic cohort of girls. Data were from The Breast Cancer and Environment Research Program at three US sites: New York City, Cincinnati, and San Francisco Bay. Girls were enrolled at ages 6-8 years in 2004-2007. Girls with PbB collected at  $\leq 10$  years old (mean 7.8 years, standard deviation (SD) 0.82) and  $\geq 3$  follow-up visits were included (n=686). The geometric mean of PbB was 1.03 ug/dL (95% Confidence Interval (CI): 0.99, 1.06) and was dichotomized as "low",  $< 1$  ug/dL (n=344) and "high",  $\geq 1$  ug/dL (n=342). Anthropometric measurements of height, body mass index (BMI), waist circumference (WC), and percent body fat (%BF) were collected at enrollment and follow-up visits through 2015. Linear mixed effects regression, adjusted for race/ethnicity, estimated how PbB related to changes in girls' measurements from ages 7-14 years. At 7 years, mean difference in height was -2.1 cm (95% CI: -3.1, -1.0) for girls with high versus low PbB; differences decreased with age to -1.4 cm (95% CI: -2.5, -0.33) at 14 years. Mean differences for BMI, WC, and BF% at 7 years between girls with high versus low PbB were -0.82 kg/m<sup>2</sup> (95% CI: -1.3, -0.30), -2.3 cm (95% CI: -3.9, -0.65), and -2.2% (95% CI: -3.6, -0.76), respectively. Overall, these differences persisted or decreased with advancing age and at 14 years, differences were -0.69 kg/m<sup>2</sup> (95% CI: -1.5, 0.08), -2.8 cm (95% CI: -4.9, -0.70), and -1.6% (95% CI: -2.9, -0.24) for BMI, WC, and BF%, respectively. These findings suggest that higher levels of PbB during childhood, even though relatively low by screening standards, may be inversely associated with anthropometric measurements in girls throughout early adolescence.

## **P02.2700. Newborn Measures of Persistent Chemicals and Early Childhood Growth**

Edwina Yeung

**Abstract:** Measurable levels of potentially obesogenic persistent endocrine disruptors remain detectable in pregnant women and newborns. However, few data on newborn exposures prospectively capture childhood growth. Using a novel pooling approach to ensure quantification of environmental chemicals in newborn dried blood spots (DBS), we measured dichlorodiphenyldichloroethylene (DDE), polybrominated diphenyl ether congener 47 (PBDE47), and 10 polychlorinated biphenyl (PCB) congeners for 2,065 (53%) singleton infants participating in Upstate KIDS. Chemicals were measured by gas chromatography-DFS high resolution mass spectrometry. To reach limits of detection, materials from 5 DBS were eluted, pooled and assayed together. We imputed individual level data from measured pools assuming gamma distributions appropriate for the skewed chemical exposures. Children's longitudinal weight and height data were captured on journals designed for parents to complete following pediatric visits through 36 months. Weight gain was evaluated by taking the weight at 4 and 12 months minus birthweight. Rapid gain was then defined as weight gain above 0.5 and 0.67 standard deviation scores from the mean at 4 and 12 months, respectively (cut points associated with fatty liver). Obesity was defined as a 24-36 month BMI greater than 90th percentile for age. Logistic regression was used to estimate odds ratios (OR) and 95% confidence intervals (CI) adjusting for confounders including pre-pregnancy BMI. Higher levels of PCB congeners 18 and 28 were associated with rapid weight gain at 4 months (aOR: 1.15; 1.02-1.29; 1.06: 1.01-1.12 per ng/ml increase in concentrations, respectively), but not at later ages. PCB #153 was associated with risk of rapid weight gain only at 12 months (aOR: 1.09; 1.01-1.19 per ng/ml). None of the associations were robust to correction for multiple comparisons ( $p < 0.005$ ). In conclusion, low levels of persistent chemicals at birth were not associated with early childhood obesity.

## **P02.2710. Relative Uptake of Methylmercury was Higher in the Brain of Fetal and Neonate than Weanling and Adult Rats**

Abstract: Fetuses and neonates are known to be highly susceptible to methylmercury (MeHg) toxicity. However, little is known about the relative uptake of MeHg from blood to the developing brain compared to adults. We measured time-course changes in MeHg concentrations in the brain of fetal, neonate, weanling, and adult rats following a single MeHg administration. In the experiment at late gestation, MeHg (0.08 mg Hg/kg) was subcutaneously injected to dams on embryonic days 17, 18, 18.5, 19, 19.5, and 20, and the dams and fetuses were dissected on embryonic day 21 (1 day before parturition). Hg concentrations were measured 1, 1.5, 2, 2.5, 3, and 4 days after the injection. Brain Hg levels in fetuses peaked 2 days after the injection and were approximately 1.5 times higher than levels in dams during that period. In the experiment at postnatal periods, the same dose of MeHg was injected subcutaneously to male pups on postnatal day 1 (neonate), 35 (weanling), and 56 (adult). The rats were then sacrificed 1, 2, 3, 4, 5, and 6 days after injection. Brain Hg levels peaked most rapidly in neonates, and levels were approximately 1.5 times higher than levels in weanling or adult rats. Throughout the experiment of the pregnancy and postnatal periods, the Hg level in the blood and Hg brain/blood ratio 24 h after MeHg injection were highest in fetuses, followed by neonates, and decreased with life stage. These results indicate that relative higher brain uptake of MeHg is an important factor for increased vulnerability of fetuses and neonates to MeHg poisoning.

## **P02.2720. Prenatal Exposure to a Mixture of Persistent Organic Pollutants (POPs) and Child Reading Skills at School Age**

Aimin Chen

**Abstract:** Background: Prenatal exposure to POPs may affect child neurobehavior, however, exposures to mixtures of POPs have rarely been examined. Methods: We estimated associations of prenatal serum concentrations of 17 POPs, including 5 polybrominated diphenyl ethers (PBDEs), 6 polychlorinated biphenyls (PCBs), p,p'-DDE, p,p'-DDT, and 4 polyfluoroalkyl substances (PFAS), in relation to Wide Range Achievement Test-4 reading composite scores at age 8 years in 161 children from a pregnancy/birth cohort (HOME Study, 2003-present) in Cincinnati, OH. We applied six statistical methods: least absolute shrinkage and selection operator (LASSO), elastic net (ENET), Sparse Principal Component Analysis (SPCA), Weighted Quantile Sum (WQS) regression, Bayesian Kernel Machine Regression (BKMR), and Bayesian Additive Regression Trees (BART), to estimate covariate-adjusted associations with individual and multiple POPs. Results: Both LASSO and ENET models showed inverse associations with reading scores for BDE-153 and BDE-28, and positive associations for CB-118, CB-180, PFOA, and PFNA. The SPCA identified inverse associations for BDE-153 and BDE-100 and positive associations for all PFAS, as parts of different principal score mixtures. The WQS regression suggested high weight for BDE-100 and BDE-28 (0.34 and 0.17) in the inverse association model and high weight for PFNA and CB-180 (0.28 and 0.21) in the positive association model. The BKMR model identified BDE-100 and BDE-153 for inverse associations and CB-118, CB-153, CB-180, PFOA, and PFNA for positive associations. The BART method found dose-response functions similar to the BKMR model. No effect modifications between POPs were identified. Conclusions: Despite some inconsistency in congeners, these analyses revealed inverse associations between prenatal PBDE concentrations and children's reading skills. Positive associations between PCB congeners and PFAS and reading skills were also found, but residual confounding cannot be ruled out.

## **P02.2730. Prenatal Lead Exposure and Elevated Blood Pressure in Children**

Shohreh Farzan

**Abstract:** Growing evidence suggests that environmental exposures can influence blood pressure over the course of a lifetime. Exposure to toxic metals has been associated with increased blood pressure in adults, but few studies have examined the impacts of in utero and early life toxic metals exposure on blood pressure in childhood. As subclinical vascular changes are thought to begin early in life, it is possible that in utero toxic metals exposure may play a role in blood pressure homeostasis. As part of the ongoing New Hampshire Birth Cohort Study, we investigated the association between in utero Pb exposure and early childhood measures of blood pressure in 287 children at 5 years of age. Pb was measured in maternal toenail samples collected at 28 weeks gestation and 6 weeks postpartum, which represent exposures ~6 to 9 months prior to collection and therefore reflect the early prenatal and late prenatal exposures, respectively. Blood pressure was assessed as systolic blood pressure (SBP), diastolic blood pressure (DBP), mean arterial pressure (MAP), pulse pressure (PP) and pulse rate, for which 3 to 5 measurements of each were recorded and averaged. In preliminary linear regression analyses, adjusted for child age, sex, height, and weight, we observed that a doubling of maternal prenatal toenail Pb was associated with statistically significant increases in child SBP (0.88 mmHg, 95% CI: 0.13, 1.62), MAP (0.57 mmHg, 95% CI: 0.04, 1.10) and PP (0.59 mmHg, 95% CI: 0.01, 1.16). Exploratory analyses stratified by sex suggest that these effects may be stronger among boys, particularly for SBP and MAP. Our preliminary results begin to suggest that in utero Pb exposure may be associated with early life cardiovascular effects in children, which could have consequences for long-term health.

## **P02.2740. Transplacental Transfer Efficiency and Blood Partitioning of Perfluoroalkyl Substances**

Dania Valvi

*Dania Valvi<sup>1</sup>, Berrak Eryasa<sup>3</sup>, Philippe Grandjean<sup>1</sup>, Flemming Nielsen<sup>4</sup>, Denis Zmirou-Navier<sup>3</sup>, Elsie Sunderland<sup>1</sup>, Pal Weihe<sup>2</sup>, Youssef Oulhote<sup>1</sup>*

- 4. University of Southern Denmark, Odense, Denmark.*

**Abstract:** Background: Recent studies have established the ability of perfluoroalkyl substances (PFASs) to pass through the placenta, however data on PFAS transfer efficiency and blood partitioning are limited. Aim: We evaluated transplacental transfer and blood partitioning of 16 PFASs detected in maternal serum, cord serum and cord whole blood, as well as the associations of mother-newborn characteristics with PFAS transfer efficiency and blood partitioning. Methods: We examined 151 mother-child pairs from two Faroese cohorts born in 1999-2001 and 2008-2009. Cord:maternal serum (transplacental transfer ratio [TTR]) and cord serum:whole blood (blood partitioning) ratio were estimated for 9 perfluorocarboxylates, 4 perfluorosulfonates and 3 precursor compounds. Multivariable regression analyses assessed the associations of potential predictors (i.e., cohort, maternal age, parity, gestational diabetes, sex and birthweight) with the ratios. Results: Correlations between maternal and cord serum concentrations were moderate to high for all PFASs ( $\rho$ : 0.41 to 0.95), indicating significant transfer from mother to fetus. Median TTRs ranged from 0.36 (PFDA and PFUnDA) to less than 1 for all PFASs, except FOSA (TTR: 1.21). All PFASs had higher concentrations in serum than whole blood, except FOSA and PFHpA, with partitioning ratios from 0.36 (FOSA) to 2.75 (PFUnDA). PFAS family and carbon chain length were important predictors of transfer and blood partitioning ratios, with U-shaped relationships seen between TTRs and carbon chain length. We also found significantly higher transplacental transfer to newborns of mothers diagnosed for gestational diabetes (adjusted ratio increases between 23% and 44% depending on PFAS). Conclusions: This study suggests that transplacental transfer and blood partitioning depends on PFAS family, carbon chain length and mother-newborn characteristics, such as gestational diabetes. These findings can improve PFAS exposure risk assessment in epidemiologic studies.

**P02.2750. Early Descriptive Results from the Maternal and Developmental Risks from Environmental and Social Stressors (MADRES) Pregnancy Cohort Study**

Theresa Bastain

Abstract: In recent decades, the prevalence of adult and childhood obesity has dramatically increased in the United States. The burden of this increase in prevalence been shown to disproportionately affect specific racial and ethnic groups. While diet and physical activity are significant determinants of childhood and adult obesity, environmental exposures are increasingly important, yet poorly understood, contributors to obesity. The "Maternal And Developmental Risks from Environmental and Social Stressors (MADRES)" study is a prospective pregnancy cohort of 1000 predominantly lower-income, Hispanic woman-infant dyads in Los Angeles focused on understanding determinants of childhood and pregnancy-related obesity. Enrollment in the MADRES cohort is initiated prior to 30 weeks gestation primarily through partner community health clinics in Los Angeles. Cohort participants are followed through their pregnancies, deliveries, and through their infants' first year of life with a combination of in-person study visits with extensive biospecimen collection and phone questionnaire follow-up. Among the first 208 pregnant women enrolled, 82% self-report Hispanic ethnicity, 40% are predominantly Spanish speaking, 75% report an annual household income of less than \$30,000 and 59% have at most a 12th grade education. Selected pre-pregnancy and pregnancy health characteristics as well as environmental and household characteristics will also be presented. The MADRES cohort study is uniquely positioned to identify key environmental, social and health targets for policy, clinical and programmatic intervention to improve the health of medically-underserved women and children in urban Los Angeles.

## **P02.2760. Prenatal Triclosan Exposure and Thyroid Hormones Measured at Birth**

Kylie Wheelock

*Kylie Wheelock<sup>1</sup>, Nadia Bokhari<sup>1</sup>, Ya Wang<sup>2</sup>, Millie Tung<sup>1</sup>, Shuang Wang<sup>2</sup>, Frederica Perera<sup>1</sup>, Julie Herbstman<sup>1</sup>*

*2. Department of Biostatistics, Columbia University, New York, NY, United States.*

**Abstract:** Triclosan (TCS) is an antibacterial compound introduced in 1972 and used in personal care products including soaps, cosmetics, and toothpastes. It has been shown to disrupt thyroid pathways; thus, exposure among pregnant women is concerning, given the role of thyroid hormones in early brain development. Although TCS was banned by the U.S. Food and Drug Administration in 2016 in soaps, it is still present in toothpastes, deodorants, and shave gels. The literature is inconsistent on the association between TCS exposure and thyroid hormones. We analyzed the association between prenatal TCS exposure and Thyroxine (T4), Free Thyroxine (FT4) and Thyroid Stimulating Hormone (TSH), in cord blood from participants in a prospective cohort study in New York City. Women were enrolled into the Columbia Center for Children's Environmental Health (CCCEH) cohort from 1998-2006. TCS was measured in a spot urine sample collected in the third trimester. Relevant covariates were assessed by questionnaire or medical records. Umbilical cord thyroid hormones were measured for T4, FT4, and TSH. Among N=165 women with both TCS and thyroid hormone measures available, we used linear regression to assess the effects of TCS on thyroid hormones. TCS was detected in 80.5% of CCCEH urine samples with a median concentration of 8.4 ng/mL, after adjusting for urinary dilution. We found significant negative associations between prenatal TCS exposure and T4 ( $\beta = -2.69$ ,  $p=0.01$ ) and TSH ( $\beta = -0.08$ ,  $p=0.03$ ). The associations were strengthened after removing women with planned caesarian sections and restricting to women who went through labor (N=146), T4 ( $\beta = -3.47$ ,  $p=0.003$ ) and TSH ( $\beta = -0.104$ ,  $p=0.014$ ). confirmed, the continued use of TCS should be re-evaluated. We found detectable concentrations of TCS among women who were pregnant before the U.S. FDA ban and significant associations between prenatal TCS and thyroid hormones measured in cord blood. Additional research is needed to confirm the associations.

## **P02.2770. Maternal Race and Fetal Sex Modify the In-Utero Developmental Toxicity of Phthalates**

Michael Bloom

*Michael S. Bloom<sup>1</sup>, Rebecca J. Wineland<sup>2</sup>, Abby G. Wenzel<sup>2</sup>, John W. Brock<sup>3</sup>, John R. Kucklick<sup>4</sup>, Celeste D. Butts<sup>1</sup>, Recai Yucel<sup>5</sup>, Roger B. Newman<sup>2</sup>*

- 5. Epidemiology & Biostatistics, University at Albany, SUNY, Rensselaer, NY, United States.*

**Abstract:** Experimental data implicate phthalates as developmental toxicants. Despite ubiquitous human exposure, there are few data assessing the risks of gestational exposure on fetal development. To address this gap, we enrolled 310 black (n=152) and white (n=158) pregnant women, with uncomplicated, singleton live births. Women completed an exposure questionnaire and provided up to 2 urine specimens during pregnancy. We abstracted birth data from the hospital records. We measured 8 urinary phthalate metabolites (ng/mL) and evaluated associations with preterm birth (PTB, <37 weeks' gestation), low birth weight (LBW, <2500 g), birth weight for gestational age (z-score), and small for gestational age (SGA, <10th %tile), adjusted for confounders. We tested for interactions by maternal race and infant sex. We detected an interaction for MEP with PTB (p=.02), with greater risk among blacks (OR=1.43 95%CI=.96, 2.12) compared to whites (OR=.62 95%CI=.34, 1.13). MMP was associated with higher LBW risk (OR=1.90 95%CI=1.11, 3.25), and sex interactions revealed a greater risk of LBW for boys with MBP (p=.002), MiBP (p=.02), MBzP (p=.01), MEP (p=.002), and MMP (p=.09). Lower z-scores were associated with MiBP ( $\beta$ =-.28 95%CI=-.54, -.02) and MMP ( $\beta$ =-.31 95%CI=-.52, -.09) while MEP interacted with race (p=.03), indicating an effect among whites ( $\beta$ =-.14 95%CI=-.28, .001) but not blacks ( $\beta$ =.05 95%CI=-.09, .50). MiBP (OR=2.84 95%CI=1.22, 6.61) and MEOHP (OR=2.79 95%CI=1.05, 7.41) were associated with higher SGA risk. Interactions (p=.09) indicated higher SGA risk for MEHP in whites (OR=3.22 95%CI=.63, 16.39) than in blacks (OR=.71 95%CI=.07, 7.11), and different MBP (p=.04) and MiBP (p=.02) effects, respectively, in boys (OR=2.00 95%CI=.46, 8.70 and OR=2.54 95%CI=1.00, 6.46) and girls (OR=.80 95%CI=.22, 2.97 and OR=3.52 95%CI=1.22, 10.14). Our results suggest that gestational phthalate exposures increase risks for PTB, LBW, and restricted fetal growth, however, the effects vary by race and sex.

## **P02.2780. Phthalate Exposure during Pregnancy and Long-Term Weight Gain in Women**

*6. Division of Research in Community Interventions, National Institute of Perinatology, Mexico City, Mexico.*

**Abstract:** Background: Phthalates are man-made chemicals commonly used in the manufacture of industrial and home products. As they are non-covalently bound to these products, they are easily released into the environment during their manufacture, use and disposal. For this reason, exposure to phthalates is widespread, including among pregnant women. Phthalates are known endocrine disruptors and peroxisome proliferator-activated receptor activators (PPAR $\alpha$ , PPAR $\beta$ , PPAR $\gamma$ ), potentially capable of promoting an obesogenic effect. The aim of the present study was to evaluate the association between phthalate exposure during pregnancy and long-term weight gain in women. Methods: Urinary phthalate determinations, socioeconomic, anthropometric and diet information from 229 women from the Early Life Exposure in Mexico to Environmental Toxicants (ELEMENT) birth cohort were collected during pregnancy. Maternal anthropometric information (body weight, height), was also collected five times within the first year postpartum and twice during follow-up visits 5-10 years later. A path analysis was performed to assess the association pattern between urinary phthalate metabolite levels during pregnancy and change in weight (kg) per year after delivery, including age, education, with/without partner, parity, energy intake and breastfeeding duration. Results: Mono-3-carboxypropyl phthalate (MCP) was associated with a mean increase in weight per year of 0.33 kg (95% CI: 0.09, 0.56); and mono-benzyl phthalate (MBzP) with a mean decrease in weight per year of 0.21 kg (95% CI: -0.38, -0.03). Conclusion: Exposure to certain phthalates during pregnancy might play a role in metabolic changes in women, resulting in long term weight change. This is the first study to evaluate phthalate exposures during pregnancy and long-term weight change in women. More studies on the effects of phthalate exposure during this vulnerable stage in women's health are required.

## **P02.2790. Mixed Metal Exposures and Early Childhood Development**

**Abstract:** Background. Children are exposed to multiple chemicals in the environment, including metals such as Pb, As, and Mn. These exposures often occur concomitantly with over- or under-nutrition. We aimed to investigate the associations between mixed environmental exposures and early childhood nutrition status among cohorts of children in Bangladesh and rural New Hampshire. Methods. Child participants from Bangladesh are members of a longitudinal birth cohort established to study the health effects of prenatal and early childhood exposures to metals in the environment; New Hampshire participants are members of the New Hampshire Birth Cohort Study, established to explore the effects of fetal exposure to environmental contaminants. In Bangladesh, umbilical cord blood samples were collected at birth, and blood samples were collected via venipuncture at age 20-40 months. Children with height for age <-2 z-scores below the median of the WHO Child Growth Standards were classified as stunted in all analyses. A multivariable GAM was constructed using tensor product smoothing,  $ti()$ , to test for interactions between metal mixtures. Similar methods are being applied to our New Hampshire Birth Cohort. Results. In Bangladesh, median (IQR) venous blood Pb, Mn and As levels were 5.7 (3.8-8.8), 2.0 (1.5-2.5) and 0.7 (0.3-1.3)  $\mu\text{g/dL}$ , respectively. Results of the GAM highlighted a significant main effect of each individual metal on early childhood stunting (p-values: As = 0.02; Mn = 0.004; Pb = 0.04) and a significant As/Mn interaction (p-value = 0.02). Evidence of a significant As/Mn interaction (p-value = 0.02) was found. Conclusions. Blood Pb and As concentrations were independently associated with increased risk of stunting at 20-40 months; Mn exposure was associated with decreased stunting in rural Bangladesh. Mn exposure decreased the risk associated with As in our Bangladeshi cohort, demonstrating the ability for individual main effects of metals to operate synergistically in a mixture.

## **P02.2800. Distribution and Predictors of Toxic and Essential Metals in the Cord Blood of Chinese Newborns**

Monica Silver

**Abstract:** Introduction: Prenatal and childhood heavy metal exposures are associated with developmental effects in childhood. In contrast, trace metals are essential for proper growth and development and deficiencies or excesses of these metals can similarly have negative health effects. Here we determined the concentrations of 20 heavy metals and trace elements in umbilical cord blood and identified demographic predictors of exposure. Methods: 20 metals were measured in the umbilical cord blood (plasma-Al, Sb, As, B, Ba, Cd, Co, Cr, Cs, Cu, Hg, Mn, Mo, Ni, Rb, Se, Sr, Ti, Zn; whole-Pb) of 357 infants from Zhejiang Province, China. Relationships between demographic variables and metals were analyzed using generalized linear models and logistic regression. Results: 10 metals (Sb, Co, Cs, Cu, Pb, Mo, Rb, Se, Sr, Ti, Zn) were detected in all samples. Parental occupation and season of birth were the strongest predictors of metals in infant cord blood. Infants whose mothers worked outside the home had 0.3 µg /L higher logHg in their cord blood, compared to those who were housewives ( $\beta$ [95% CI]=0.30[0.06, 0.55],  $p=0.02$ ). Infants whose fathers were managers had 0.6 µg/L higher logBa in their cord blood, compared to those with professional/administrative jobs ( $\beta$ [95% CI]=0.63[0.09, 1.16],  $p=0.02$ ). Infants born in the spring had 0.1-0.2 µg/L higher logAs and logCo in their cord blood ( $\beta$  [95% CI] = 0.22 [0.01, 0.42],  $p=0.04$ ; 0.11 [0.01, 0.22]),  $p=0.04$ ), while infants born in the summer had higher Sb, logB, logHg, and logZn ( $\beta$  [95% CI] = 0.74 [0.24, 1.24],  $p=0.004$ ; 0.11 [0.00, 0.21],  $p=0.04$ ; 0.29 [0.08, 0.49],  $p=0.007$ ; 0.18 [0.06, 0.31],  $p=0.005$ ), compared to those born in fall/winter. Conclusions: Parental occupation and season of birth were the strongest predictors of metals in umbilical cord blood across analyses. Prenatal exposure to toxic heavy metals and early-life trace metal deficiencies have been associated with negative developmental effects and are concerns worldwide.

**P02.2810. Temporal variability of urinary phenol concentrations with use of personal care products in pregnant women**

Rémy Slama

*Dorothy Nakiwala<sup>1</sup>, Rémy Slama<sup>1</sup>, Claire Philippiat<sup>1</sup>*

*1. Institute for Advanced Biosciences (IAB), INSERM U1209, CNRS UMR 5309, Université Grenoble Alpes, La tronche, France.*

**Abstract:** Background/Aim: Some phenols are endocrine disruptors commonly used in production of personal care products (PCP). These compounds have a short half-life and past studies have reported detection of some parabens in urine as early as 3 hours after use of PCP. This study aimed at assessing temporal effects of PCP use on urinary concentrations of phenols in an intra-individual study considering shorter and multiple time windows of exposure. Methods: We assayed concentrations of 10 phenols in 114 urine samples from 2 pregnant women collected over a week. Participants also filled detailed diaries with exact time of use of 16 PCP and time for urine collection. We characterized use of PCP as, a) use of a specific PCP (yes/no) b) sum of PCP used in each time window, categorized in 3 percentiles. We used linear mixed models to examine the association between the sum and single PCP use in 6, 12 or 24 hours prior to urine collection and urinary phenol concentrations. Results: Sum of PCP use was associated with increased urinary concentrations of the parabens. The implicated parabens varied by time-window of exposure, in 6 hours, ethyl and butyl paraben, in 12 hours, propyl paraben and in 24 hours, methyl and propyl paraben. Single use of coloured cosmetics, deodorant, shampoo, conditioner and face cream was also associated with increased urinary concentrations of parabens across the 3 time windows. We did not observe clear associations with the other phenols; bisphenol A and S, 2,4 and 2,5 dichlorophenols, benzophenone-3 and triclosan. Conclusion: These results elaborate further that PCP are important sources of exposure to parabens in pregnant women and that effects of PCP use on the 4 paraben urinary concentrations varied by time window of exposure.

## **P02.2820. Pyrethroid Pesticide is Associated with Attention Deficit/Hyperactivity Disorder Symptom in 4-Year Old Children**

Wooseok Lee

Wooseok Lee<sup>1</sup>, Youn-Hee Lim<sup>1</sup>, Bung-Nyun Kim<sup>1</sup>, Choong Ho Shin<sup>1</sup>, Young Ah Lee<sup>1</sup>, Inhyang Kim<sup>1</sup>, Yun-Chul Hong<sup>1</sup>

1. *Seoul National University College of Medicine, Seoul , Korea (the Republic of).*

**Abstract:** Background: Using pyrethroid insecticides has increased rapidly over the past decade. Pyrethroid pesticides are known to be able to cause abnormalities in the dopamine system and affect an Attention Deficit/Hyperactivity Disorder (ADHD) phenotype in animal experiments. However, studies about their potential health effects, especially on children, are limited. In this study, we assessed the association between use of pyrethroid insecticides and ADHD symptom in 4-year old children. Methods: We conducted an analysis of 385 participants in Environment and Development of Children (EDC) Study who were 4 years old from 2014 to 2015. Creatinine adjusted 3-PBA concentration was measured in children's urine at 4 years of age. We assessed the association between urinary 3-PBA concentration and using pyrethroid insecticides from living environment questionnaire and also assessed the association between urinary 3-PBA concentration and ADHD symptom through generalized estimating equations (GEE). Results: The mean 3-PBA concentration in children's urine at 4 years of age was 2.267  $\mu\text{g/g}$  creatinine. Natural log transformed 3-PBA concentration was significantly associated with children's ADHD symptom ( $\beta = 0.057$ ,  $P = 0.003$ ). When stratified by gender, it was significant in boys but not in girls. Higher urinary 3-PBA concentration was significantly associated with using pyrethroid pesticide ( $\beta = 0.339$ ,  $P = 0.009$ ). Conclusion: Our study results indicate that urinary 3-PBA concentration in 4-year old children increases the risk of developing ADHD. As the use of pyrethroid pesticides is increasing, more attention should be paid to their health effects.

## **P02.2830. Impacts of Prenatal Polycyclic Aromatic Hydrocarbons Exposure on Cancer-Related Gene Expression of Fetus**

**Abstract:** Objective To explore the effects of prenatal polycyclic aromatic hydrocarbons (PAHs) exposure on genome-wide mRNA expression, and to screen the major PAHs that make the largest contribution to variance of gene expression of fetus. Methods Seven carcinogenic PAHs in cord serum were detected using high-performance liquid chromatography (HPLC)/fluorescence. Affymetrix microarray was used to test the variance of genome-wide mRNA expression of cord blood. The relationships of prenatal PAHs exposure and the expression level of cancer-related genes, and the contribution of prenatal PAHs exposure to variance of cancer-related genes expression were analyzed. Results Seven carcinogenic PAHs could be detected in about more than 70% of cord serum samples. 1847 genes were declared to be significantly differentially expressed among 5 groups with different PAHs levels and the tumor-related pathways predominated in the pathway-network. Significant correlations between cord serum PAHs levels and mRNA expression levels of genes of SNRPN, RPL27A, BMP1, NUDT2, E2F1 and RAD54B were discovered ( $p < 0.05$ ). BbF had the most association with gene expression, and then were BkF and BaP. Conclusion Six cancer related genes can be identified as candidate target genes of prenatal PAHs exposure, and BbF, BkF and BaP were in the key position on affecting expression of the six cancer related genes.

## **P02.2840. Prenatal Lead Exposure and Cord Blood Methylation: An Epigenome-Wide Association Study in the Mexican Progress Cohort**

Jonathan Heiss

*Jonathan Heiss<sup>1</sup>, Andrea Baccarelli<sup>2</sup>, Martha M. Téllez-Rojo<sup>5</sup>, Guadalupe Estrada<sup>3</sup>, Lourdes Schnaas<sup>3</sup>, Lifang Hou<sup>4</sup>, Chitra Amarasiriwardena<sup>1</sup>, Katherine Svensson<sup>1</sup>, Robert Wright<sup>1</sup>, Allan Just<sup>1</sup>*

*5. Center for Nutrition and Health Research, National Institute of Public Health, Cuernavaca, Mexico.*

**Abstract:** Background: Lead is a paradigm toxicant in children yet little is known about its epigenetic effects. Previous studies reported associations between lead exposure during pregnancy and cord blood methylation levels. It is however unclear during which developmental stage lead exposure is most harmful. The aim of this study was to investigate the possible impact and window of susceptibility of lead on cord blood DNA methylation. Methods: Cord blood methylation levels were assayed in 448 children from a Mexican birth cohort using the Infinium MethylationEPIC microarray. Lead concentrations were measured in umbilical cord blood as well as in blood samples from the mothers collected at 2nd and 3rd trimester and delivery using inductively coupled plasma-mass spectrometry and maternal bone lead levels in tibia and rotula using X-ray fluorescence. Comprehensive quality control and preprocessing of microarray data was followed by an unbiased restriction to 204,567 CpG sites with substantial variance. Robust methods were used to regress the methylation levels at every CpG site on each exposure additionally adjusting for leukocyte composition, batch variables, gestational age and weight z-scores, maternal age and education, parity and mode of delivery. Results: Testing the association between the 6 lead exposures and 204,567 CpG sites, no significant hits were found at a 5% false discovery rate. Conclusions: While sample size was larger (1.4× at 3rd trimester) and average lead levels and standard deviation thereof were higher (3.2× and 4.3×, respectively) than in a similar epigenome-wide association study, the number of tested association was 3.1× higher as well. The study had an 80% power to detect correlations >0.21. Nonetheless, this null result might be due to the lack of statistical power. Future work will consider more powerful statistical approaches that jointly combine proximal methylation sites that may be co-regulated.

## **P02.2850. Perfluoroalkyl Substances and Thyroid Function in Pregnant Women and their Offspring**

**Abstract:** Background: Normal thyroid function during pregnancy is critical for fetal development. Experimental studies suggest that certain perfluoroalkyl substances (PFAS) may disrupt thyroid function but findings from observational studies have been inconsistent. Aim: To examine the association between maternal PFAS concentration in pregnancy with 1) maternal thyroid function in pregnancy and 2) offspring thyroid function 20 years later. Methods: In a cohort of Danish pregnant women who gave birth in 1988-89 concentrations of PFAS, thyroid stimulating hormone (TSH) and free thyroxine (FT4) were quantified in 876 women using samples from week 30 of gestation. TSH and FT4 concentrations were also quantified in 411 offspring 20 years later. Results: The median concentrations of PFHxS, PFOS, PFOA, PFNA and PFDA were 0.35 ng/mL, 21.5 ng/mL, 3.7 ng/mL, 0.34 ng/mL and 0.05 ng/mL, respectively. In pregnancy concentrations of PFNA were associated with around 14% higher maternal TSH concentrations (95% CI: 10%, 30%) when comparing the highest to lowest quartile of exposure (p for trend=0.04). Non-significant but positive associations were observed for the other compounds and no associations were observed with maternal FT4. Prospectively maternal concentrations of PFOA were associated with around 24% higher (95%CI: 8%, 43%) TSH concentrations in the offspring at 20 years when comparing the highest to lowest quartile of maternal PFOA exposure (p for trend = 0.01). A modest non-significant association was observed for PFOS (p for trend = 0.13). No associations were observed for the other compounds and no associations were observed with offspring FT4 concentrations. Conclusion: Except for PFNA no clear link was observed between circulating PFAS concentrations and thyroid function in pregnancy. Prospectively, there were some indications that maternal PFOA concentrations may be associated with higher offspring TSH concentrations at 20 years but replication is needed to exclude chance findings.

## **P02.2860. Self-Reported Oil Spill Exposure and Birth Outcomes: The Growth Study**

Emily Harville

*Emily W. Harville<sup>1</sup>, Arti Shankar<sup>1</sup>, Leah Zilversmit Pao<sup>1</sup>, Wei-Hsin Hsiao<sup>1</sup>, Maureen Y. Lichtveld<sup>1</sup>, Pierre Buekens<sup>1</sup>*

*1. Tulane University, New Orleans, LA, United States.*

**Abstract:** Background: The chemical, economic, and social effects of a major oil spill might affect pregnancy health. Methods: Between 2012 and 2016, 1444 women reported their involvement with the 2010 Gulf of Mexico oil spill, as well as at least one livebirth. Indicators of oil spill exposure included financial consequences, direct contact with oil, traumatic experiences, loss of use of the coast, and involvement in litigation. Birth outcomes studied were low birthweight (LBW; birthweight <2500 g) and preterm birth (PTB; >3 weeks early), either obtained as self-reported information or abstracted from medical records if the woman was still pregnant at the time of the interview. All pregnancies prior to the oil spill were considered unexposed; those after the oil spill were considered exposed or unexposed depending on interview responses. Generalized estimating equations with a logit link and adjustment for confounders were used to assess the relationship between oil spill exposure and these outcomes. Results: 370 (13.2%) of pregnancies were reported as ending in LBW, while 273 (9.7%) as ending in PTB. Births after the oil spill were not more likely to end in either outcome (adjusted odd ratio, 0.96, 95% CI 0.73-1.24 and 0.98, 0.72-1.33). Financial consequences, trauma, use of coast, and litigation were not associated with worse birth outcomes (ORs between 0.8 and 1.2). Risk of preterm birth was raised in the group with most contact with oil (aOR 2.30, 1.16-4.59), although sensitivity analyses did not indicate this result was robust to other assumptions. Conclusions: Self-reported exposure to most aspects of the Gulf oil spill were not associated with adverse birth outcomes. The raised risk for PTB among those in contact with oil warrants examination in studies with more detailed assessment of exposure.

## **P02.2870. Associations between Organophosphate Flame Retardant Exposure during Pregnancy and Reproductive and Thyroid Hormone Levels: A Preliminary Analysis**

Deborah Watkins

*Deborah Watkins<sup>1</sup>, Zaira Rosario<sup>2</sup>, Jose Cordero<sup>3</sup>, Akram Alshawabkeh<sup>4</sup>, John Meeker<sup>1</sup>*

*1. University of Michigan School of Public Health, Ann Arbor, MI, United States.*

*2. University of Puerto Rico, San Juan, PR, United States.*

*3. University of Georgia, Athens, GA, United States.*

*4. Northeastern University, Boston, MA, United States.*

**Abstract:** The use of organophosphate flame retardants (PFRs) in consumer products has increased in recent years due to the phase out of polybrominated diphenyl ethers. As a result, exposure to PFRs is widespread, with uncertain impacts on health. A previous study of pregnant women undergoing in vitro fertilization found that higher urinary PFR metabolites were associated with decreased treatment success, while another reported associations between a PFR and increased thyroid hormone in women. Therefore, we aimed to investigate relationships between PFR exposure and serum hormone levels among a subset of pregnant women enrolled in the Puerto Rico Testsite for Exploring Contamination Threats (PROTECT) birth cohort (n=148). We measured 7 PFR metabolites (bis-2chloroethyl phosphate (BCeP), bis-(1-chloro-2propyl) phosphate (BCPP), bis(1,3-dichloro- 2-propyl) phosphate (BDCPP), di-n- butyl phosphate (DNBP), di-benzyl phosphate (DBzP), di-cresyl phosphate (DCP) and diphenyl phosphate (DPHP)) in urine samples collected at 16-20 and 24-28 weeks gestation. Testosterone (T), estradiol (E2), estriol (E3), progesterone, corticotropin-releasing hormone (CRH), sex hormone binding globulin (SHBG), thyroid stimulating hormone (TSH), T4, T3, and free T4 (fT4) were measured in serum samples collected at the same time points. We used linear mixed models to assess relationships between PFRs and hormone levels across pregnancy, adjusting for age, pre-pregnancy BMI, and specific gravity. DNBP, DBzP, and DCP were detected in <50% of samples. BCeP was associated with higher SHBG, while BDCPP was associated with higher T, E2, and fT4. BCPP was associated with lower E2, and DPHP was associated with lower T4. These preliminary findings suggest that PFRs may disrupt hormone levels during pregnancy. Further research into endocrine disruption as a mechanism by which PFR exposure during pregnancy may affect pregnancy and birth outcomes, as well as fetal and child development, is necessary.

## **P02.2880. Dental Amalgams and Risk of Gestational Hypertension in the MIREC Study**

Louopou Camara

*Louopou R. Camara<sup>1</sup>, Helen Trottier<sup>2</sup>, Tye Arbuckle<sup>3</sup>, William Fraser<sup>4</sup>*

- 4. Centre de recherche du CHUS, Department of Obstetrics and Gynaecology, Université de Sherbrooke, Sherbrooke, QC, Canada.*

**Abstract:** Background: The potential association between the presence or replacement of dental amalgams and gestational hypertension with or without preeclampsia (GH) is unclear. Objective: To assess the association between the presence or replacement of dental amalgams and the risk of GH in a prospective cohort study. Methods: We assessed dental amalgam status (presence or replacement), blood mercury concentrations, and measured blood pressure in 1909 pregnant women recruited in 10 Canadian cities between 2008 and 2011 as part of the Maternal-Infant Research on Environmental Chemicals (MIREC) Study. Blood pressure was assessed in each trimester of pregnancy and mercury concentrations in 1st and 3rd trimesters. Logistic regression analysis was performed to estimate the adjusted odds ratio (aOR) and 95% confidence intervals (CI) for the association between dental amalgam status and GH. Concurrent measures with GH were assessed through logistic generalized estimating equations. Results: Dental amalgam status was weakly and statistically correlated with blood mercury concentrations but there was no evidence of an association with GH in women having 1-4 (aOR = 1.31; 95% CI: 0.92, 1.85) or  $\geq 5$  dental amalgams (aOR = 1.32; 95% CI: 0.86, 2.04), compared to women without amalgam reported at first trimester. Dental amalgam replacement reported in the first or third trimester was similarly not associated with GH (aOR = 0.75; 95% CI: 0.40, 1.42 and aOR = 0.73; 95% CI: 0.39, 1.34, respectively). Conclusion: We found weak correlations between dental amalgams and blood mercury among pregnant women. However, the presence of dental amalgams or their replacement was not associated with a statistically significant increase in GH risk. Further studies are required to confirm these results.

## **P02.2890. Trace Elements in Human Milk from Italian Lactating Women: Comparison with Infant Formulas**

Elena Righi

*Elena Righi<sup>1</sup>, Guglielmina Fantuzzi<sup>1</sup>, Angela Ferrari<sup>1</sup>, Isabella Marchesi<sup>1</sup>, Letizia Pescarolo<sup>1</sup>, Elisabetta Casali<sup>1</sup>, Francesco Venturelli<sup>1</sup>, Annalisa Bargellini<sup>1</sup>*

*1. Department of Biomedical, Metabolical and Neural Sciences, University of Modena and Reggio Emilia, Modena, Modena, Italy.*

**Abstract:** Background: Human milk is the best source of nutrition for the newborns, and exclusive breastfeeding is recommended by WHO up to 6 months of age. It contains all the nutrients and essential trace elements necessary to ensure correct functioning of the organism. Infant formulas, the most common substitutes for human milk, usually contain nutrient levels modeled to have a composition similar to human milk. However, few recent data on nutrient levels in breast milk and infant formula are available from women living in Italy. The aim of this study was to determine the levels of five essential (Fe, Zn, Cu, Mn, Se) and four non-essential/toxic elements (Ni, Cr, Cd, Pb) in infant formulas and breast milk of women living in Modena, Italy and to compare them with recommended values. Methods: 130 samples of human milk (mature milk: 30-40 days postpartum) and a representative sample of infant formulas (0-6 months) sold in Italy were analyzed by ICP-MS in triplicate after microwave digestion. Results: Breast milk showed adequate levels of essential trace elements, despite the inter-individual variability observed, which was not influenced by women's characteristics and dietary habits. Non-essential/toxic elements content was well below the maximum tolerable limits set by the European Food Safety Authority (EFSA). In infant formulas as well, essential element levels were within the European recommended values, however, Fe and Mn levels, were significantly higher than in breast milk. Conclusions: The levels of essential micronutrients in lactating women living in Modena are suitable for the proper development of infants and no risk for excessive toxic elements intake was detected. Infant formulas show high fortification with Fe and Mn. Considering the growing evidence of cognitive development effects due to an excessive Mn intake, a deeper discussion on infants' Mn requirement is needed. According to our findings, breastfeeding should be still encouraged and recommended.

## P02. Adult Health Effects of Environmental Exposures 2

### **P02.2910. Association between Per- and Polyfluoroalkyl Substances (PFASs) and Thyroid Hormones in a High- Exposed Swedish Population**

**Abstract:** Per- and polyfluorinated compounds (PFASs) have endocrine disrupting properties. Alterations in thyroid hormone homeostasis have also been observed in animal experimental studies, and in some cross-sectional studies in the general population, often with ambiguous results, and data for other PFASs than PFOA and PFOS is scarce. In December 2013 high levels of PFASs were detected in one out of two waterworks in Ronneby, a municipality with 28000 inhabitants. This waterworks supplied 1/3 of the households. The source of PFASs was groundwater contamination from firefighting foam. This "natural experiment" enables epidemiological investigations over a wide exposure span, dominated by exposure to PFOS and PFHxS. Between 2014-15, 3285 individuals with a wide age span from the municipality and a nearby reference community participated in open blood samplings. We investigated thyroid hormone levels in this combined group, having serum levels for PFOS median 160 (10, 90 percentiles 11, 560) ng/ml, PFHxS 140 (6, 540) and PFOA 9 (2, 29) ng/ml. The associations between PFASs and thyroid hormone were assessed using linear regression in stratified groups of gender and age (2-11, 12-19, 20-49, 50+). It was found that in girls aged 2-11, there were significant positive associations between PFASs and free T3 (fT3). A doubling of PFASs level was associated with 1-2% increase. In other age groups of female, there were no significant associations. In males, no significant associations were found between PFASs and fT3 in any age groups. For fT4, a weak positive association ( $p < 0.1$ ) were observed in females aged 12-19. In boys aged 2-11, there were positive association. Statistically significant associations between PFASs and TSH were not observed in any age groups neither for females or males. In general, females were more sensitive to PFASs with respected to thyroid hormones. Prepubertal girls in this highly exposed group showed a small increase of free T3 with increasing PFAS exposure.

## **P02.2920. Association of Perfluoroalkyl Substances with Hyperuricemia and Gout**

Lina Balluz

*Franco Scinicariello<sup>1</sup>, Lina Balluz<sup>1</sup>*

*1. NCEH, CDC, Atlanta, GA, United States.*

**Abstract:** Previous population cross-sectional studies have reported a positive association of polyfluoroalkyl substances (PFASs), including perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), with hyperuricemia and chronic kidney diseases (CKD) defined as estimate glomerular filtration rate (eGFR) <60 mL/minute/1.73 m<sup>2</sup>. We investigated whether there is an association between exposure to PFAS, and serum uric acid and gout in the adult population of the (NHANES) 2009-2012 (n=3248). PFAS includes PFOA, PFOS perfluorononanoic acid (PFNA), and perfluorohexane sulfonic acid (PFHxS). Multivariate logistic regression were performed to analyze the association of PFAS with hyperuricemia and gout. Serum PFOA, PFNA, PFOS and PFHxA were analyzed as quartiles. Multivariate linear regression were performed to analyze the association of PFAS with uric acid and eGFR. Analyses were also restricted to individuals with normal eGFR. The weighted prevalence of hyperuricemia was 17.7 % (95% CI: 15.8% - 19.73%), and of self-reported gout was 3.2 % (95% CI: 2.5% - 4.1%). After adjustment for potential confounders, all four PFAS investigated were associate with increased serum uric acid and decreased eGRF. There were statistically significant associations between the highest quartile of PFOA, PFNA and PFHxS, but not PFOS, and hyperuricemia. These association were confirmed for PFOA and PFNA, when the analyses were restricted to participants with normal eGFR. The adjusted odd ratio for gout among participants in the 4th PFOA quartile was 2.80 (95% CI: 1.16, 6.74) compared the 1st PFOA quartile. The positive association was also found when the analyses excludes individuals with CKD. In this population cross-sectional analysis, we found an association between PFOA with self-reported gout. We also confirmed previous reports of an association of PFAS with hyperuricemia and decreased eGFR. Longitudinal studies examining the relationship of PFAS renal function are needed.

**P02.2940. A Lifestyle Intervention of Exercise and Diet Attenuates Obesogenic Associations of Per- and Polyfluoroalkyl Substances: Results from the Diabetes Prevention Program**

**Abstract:** Background: Per- and polyfluoroalkyl substances (PFASs) are ubiquitous synthetic chemicals, widely detected across populations and suspected endocrine disruptors. We sought to determine the extent to which PFASs are prospectively associated with weight and body size and evaluate if a lifestyle intervention modifies this association. Methods: We utilized data from the Diabetes Prevention Program trial (DPP; 1996-2001) and Outcomes Study (DPPOS; 2002-2014) of participants initially randomized to a lifestyle intervention or placebo and followed for up to 15 years. The lifestyle intervention consisted of training in diet, physical activity, and behavior modification with the major goals of achieving 7% weight loss and 150 min/week physical activity. Participants randomized to placebo received standard information about diet and exercise. We quantified six plasma PFASs at baseline and two years post randomization, and calculated total PFAS by summing the means of the two measurements. Results: In this sample, 481 participants were initially randomized to a lifestyle intervention and 476 to placebo. PFAS concentrations were not different by treatment and similar to concentrations reported for the U.S. population in 1999-2000. Each doubling in total PFAS concentration was associated with 1.03-cm increase in hip girth during DPP (95% CI: 0.18, 1.88; P=0.017), an increase of 1.80-kg in weight from baseline to 9 years post-randomization (95% CI: 0.43, 3.17; P=0.01) and greater waist circumference trajectories (P=0.001) for the placebo group. No adverse associations were observed for the lifestyle intervention group. Conclusions: Among adults at high risk for diabetes we observed that higher plasma PFAS concentration was associated with increases in weight, waist circumference and hip girth, but a lifestyle intervention attenuated these associations. Our results suggest that diet and exercise may mitigate obesogenic effects of environmental chemicals.

**P02.2960. Aluminum (Al) Level in Blood and the Risk of Amnestic Mild Cognitive Impairment (AMCI) and Alzheimer's Disease (AD): A Case-Control Study**

Jee-Eun Choi

*Jee-Eun Choi<sup>4</sup>, Hyunmee Kim<sup>1</sup>, Juhwan Noh<sup>1</sup>, Seong-Kyung Cho<sup>2</sup>, Jaelim Cho<sup>3</sup>, Jungwoo Sohn<sup>1</sup>, Woojin Kim<sup>1</sup>, Heeseon Jang<sup>1</sup>, Changsoo Kim<sup>1</sup>*

- 3. University of Auckland, Auckland, New Zealand.*
- 4. Yonsei University, Seoul, Korea (the Republic of).*

**Abstract:** Background: Aluminum(Al) is known as a potential environmental neurotoxin substance. Epidemiological studies have found the evidence of an association between aluminum exposure neurodegenerative disorders. Most of the studies tend to emphasize the association between aluminum and Alzheimer's disease(AD), while few studies have been suggesting Serum aluminum could effect on cognitive disorders including mild cognitive impairment. Thus, this study focused on finding out the association between serum aluminum level and amnestic mild cognitive impairment (aMCI) or Alzheimer's disease (AD) Method: A matched case-control study was conducted. 136 aMIC patients and 191 Alzheimer's disease patients were recruited from a university-based hospital from 2014 to 2017. Participants (N=1957) were older than 60 years and were from community based cohorts in Seoul, Incheon, Ganghwa and Wonju, South Korea. Four healthy controls for each aMCI (N=123) patients and AD patients (n=136) were randomly selected using age and sex matching method. Serum aluminum level was analyzed from the collected blood samples. Conditional logistic regression was used, adjusting for age, education level, BMI, total cholesterol, triglyceride, high-density lipoprotein cholesterol, smoking and drinking. Results : The geometric means of aluminum level in the blood was 11.16µg/L (95%CI 10.04, 12.39) in AD patients and was 8.57µg/L (95%CI 8.14, 9.03) in control group. The geometric means of aluminum level was 11.09µg/L (95%CI 10.20, 12.06) in aMIC group and 8.35µg/L (95%CI 7.91, 8.81) in its control group. The odds ratios was 2.77 (1.70-4.58) for aMCI and 2.66(1.64-4.31) for AD. Conclusions: Aluminum level in blood was positively associated with the risk of aMIC and AD.

## **P02.2970. The Involvement of Gene Expression of Heat Shock Proteins in Cd Renal Toxicity**

Jinyong Lee

*Jinyong Lee<sup>1</sup>, Maki Tokumoto<sup>1</sup>, Masahiko Satoh<sup>1</sup>*

*1. School of Pharmacy, Aichi Gakuin University, Nagoya, Aichi, Japan.*

**Abstract:** Cadmium (Cd) is an environmental contaminant that induces toxic effects in various tissues including the kidney. The kidney is the target tissue in chronic dietary Cd exposure. Proximal tubular cell damage is characterized as Cd-induced renal damage. In our previous study, DNA microarray result showed that Cd treatment not only increased the expressions of 30 genes more than 2-fold, but also decreased those of 21 genes less than a half in HK-2 human proximal tubular cells. Among the genes whose expressions were increased by Cd, several heat shock protein genes were included. Heat shock proteins are known to play important roles in protective pathway against various stresses in cells. In this study, we examined the effect of heat shock protein genes on the viability of HK-2 cells treated with Cd. HK-2 cells were treated with 5 and 10  $\mu\text{M}$  Cd for 6 h. Although the cell viability was decreased by Cd treatment, HSPA1A, HSPA1B, HSPH1, HSPA8 gene expressions were increased by Cd treatment. Next, it was examined whether knockdown of heat shock protein genes affect the HK-2 cell viability upon Cd treatment. Knockdown of HSPH1 by siRNA treatment decreased the viability of 5  $\mu\text{M}$  Cd treated HK-2 cells compared with control siRNA treatment group. Knockdown of HSPA8 by siRNA treatment decreased the viability of non-treated and 5  $\mu\text{M}$  Cd treated HK-2 cells compared with control siRNA treatment group. These results suggest that several heat shock proteins may be involved in the protective effect against Cd toxicity in HK-2 cells.

## **P02.2980. Atmospheric Metals and Cancer Incidence in the GAZEL Cohort (1996-2014)**

Emeline Lequy-Flahault

**Abstract:** Background/Aim Metals such as cadmium are acknowledged or suspected carcinogenics. Yet the association between atmospheric metals and cancer incidence has rarely been investigated, as exposure is difficult to assess. We aim to analyze the relationships between atmospheric metals and the incidence of cancer in the French general population-based cohort Gazel. Methods We used four moss biomonitoring surveys, mainly conducted in the French countryside between 1996-2011, to assess the exposure to 13 atmospheric metals including cadmium, mercury and lead, as the mean rank of the exposure at home address to each metal over the follow-up of 11,212 participants living in low and moderate population density areas with incidence of all, bladder, breast, colorectal and kidney cancer between 2001-2014. We used Cox models to derive hazard ratios for a 2000-rank increase of exposure to each atmospheric metal, adjusted for gender, socioeconomic status, alcohol and tobacco use, family status, and with age as the underlying time scale. Results We found significant associations between incidence of all cancers and As, Cd, Cu, Hg, and Zn with HR ranging from 1.05 (CI 1.01-1.08) and 1.07 (1.04-1.11); between incidence of lung cancer and Al, Cd, Cr, Cu, Fe, Hg, Ni, and Zn with HR ranging from 1.14 (1.00-1.09) and 1.25 (1.10-1.44); between incidence of bladder cancer and Al and Fe with HR of 1.14 (1.00-1.30) and 1.15 (1.00-1.31), respectively; between incidence of kidney cancer and Cd, Hg, and Zn with HR ranging from 1.20 (1.00-1.43) and 1.21 (1.01-1.44). Incident colorectal cancer was associated with exposure to Na with an HR of 1.12 (1.00-1.25). No significant association was found between incident breast cancer and atmospheric metals. Conclusions Atmospheric metals, mainly those from anthropogenic sources, are associated with incidence of all-cause, lung, and kidney cancer for participants of the Gazel cohort living in low to moderate population density areas.

## **P02.2990. Rice Consumption and Incidence of Bladder Cancer in a United States Population**

Antonio Signes-Pastor

*2. Dartmouth-Hitchcock Medical Center, Lebanon, NH, United States.*

**Abstract:** **ABSTRACT** Background: Intake of rice increases exposure to inorganic arsenic, a known bladder carcinogen, as well as arsenic species with lesser known toxicity. Methods: To investigate whether rice intake contributes to risk of bladder cancer, rice consumption was assessed using a food frequency questionnaire administered as part of a U.S. population-based case-control study of 316 bladder cancer cases and 230 controls. Total arsenic concentration in household tap water samples was measured using inductively coupled plasma mass spectrometry (ICP-MS). Odds ratios (OR) for bladder cancer associated with the frequency of rice consumption, and white and brown rice separately, and stratified by household water arsenic concentration, were estimated using logistic regression adjusted for potential confounders (i.e., age, gender, caloric consumption, cigarette smoking status, and education). Results: No overall association was observed with any versus no rice consumption (OR = 0.8, 95% confidence interval (CI): 0.5 - 1.3), nor was any association observed among those with household water < 1 µg/L arsenic. Among those with ≥ 1 µg/L water arsenic, odds ratio increased with frequency of rice consumption (OR = 0.8, 95% CI: 0.2 - 2.9 for 1-20 g/day, OR = 3.2, 95% CI: 0.8 - 13.2 for > 50 g/day, p for trend = 0.05). Associations were particularly strong among those who frequently ate brown rice. Conclusion: Our findings suggest that rice consumption may be related to the occurrence of bladder cancer among those with higher household water arsenic concentrations.

## **P02.3000. Exposures to Paraben and Triclosan and Allergic Diseases in Tokyo: A Cross-Sectional Study**

Yukihiro Ohya

*Kiwako Yamamoto-Hanada<sup>1</sup>, Motoko Mitsui<sup>1</sup>, Rhoji Hirota<sup>2</sup>, Go Muto<sup>3</sup>, Takeshi Nakamura<sup>4</sup>, Yuma Fukutomi<sup>5</sup>, Hiroyuki Nakamura<sup>6</sup>, Yukihiro Ohya<sup>1</sup>*

- 5. Sagamihara National Hospital, Kanagawa, Japan.*
- 6. Kanazawa University, Kanazawa, Japan.*

**Abstract:** Rationale: Paraben (Pb) and Triclosan (TCS) have been contained in many commodities such as soap, toothpaste, ointment, cosmetics and etc. Exposure to Pb or TCS was implicated to be a risk factor of allergic diseases. However, an epidemiological study to explore the association between exposure to Pb or TCS and allergic diseases in Japan has remained to be seen. Methods: Cross-sectional study to detect commodities containing Pb and TSC was carried out in the National Center for Child Health and Development between 2016 and 2017. We examined participants' urinary concentrations of Pb and TCS and assessed their allergic diseases by using a questionnaire (International Study of Asthma and Allergies in Childhood). Result: In statistical analysis, 223 participants (146 children and 77 adults) were included. The users of hand wash and body wash containing TCS were 5.7%. The user of commodities containing Pb were 95.6%. Children showed higher urinary Pb concentration than adults ( $p < 0.0001$ ). Participants with Atopic Dermatitis (AD) demonstrated higher urinary Pb concentration than those without AD ( $p < 0.0001$ ). The level of urinary TCS concentration was under the limit of detection in all participants. Conclusion: To the best of our knowledge, this is the first report to examine current Pb and TCS exposures among children in Japan. In our study populations, users of commodities containing TCS was very few, while exposure to Pb containing commodities was very common. Pb exposure was higher in children and AD.

## **P02.3010. Risks of Three Substance Uses, Facial Flushing, Helicobacter Pylori Infection and Upper Digestive Diseases**

I-Chen Wu

*I-Chen Wu<sup>1</sup>*

*1. Department of Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung city, Taiwan.*

**Abstract:** Background: This study examines the effects of common environmental hazards such as tobacco, alcohol (facial flushing or not), areca nut, and Helicobacter pylori infection on different upper digestive diseases. Methods: This is a multi-hospital-based endoscopy-survey cross-sectional study. Study subjects were those who aged  $\geq 20$  years, received upper endoscopies, agreed to participate, and did not have diagnosed and treated for gastric-esophagus cancers or upper digestive tract operations in outpatient clinics at four hospitals from southwestern coast of Taiwan in a period of April 2008 and December 2013. Then, they were collected the necessary personal information and were checked the status of Helicobacter pylori (HP) infection. Adjusted odds ratio (aOR) and 95% confidence interval (CI) were presented. Results: In total, 8135 subjects were analyzed. Higher cumulative amounts of alcohol consumption were at higher risk of Barrett's esophagus and esophageal squamous cell carcinoma (ESCC), higher cumulative amounts of tobacco consumption were at higher risk of peptic ulcer, and higher cumulative amounts of areca nut consumption were at higher risk of duodenitis. For facial flushing, it was the significant risk for reflux esophagitis and Barret's esophagus (aOR = 1.18 and 1.32, 95%CI = 1.07-1.31 and 1.06-1.65, respectively), but not the risk of ESCC. In addition, HP infection was consistently and significantly risk factors for gastrointestinal diseases, including peptic ulcer, gastric adenocarcinoma, and duodenitis. Conclusion: Besides the risk of of alcohol, tobacco, and areca nut for Barrett's esophagus and ESCC, peptic ulcer, and duodenitis, respectively, presence of facial flushing was the significant risk for reflux esophagitis and Barret's esophagus and HP infection was significantly risk factors for gastrointestinal diseases, including peptic ulcer, gastric adenocarcinoma, and duodenitis.

**P02.3020. Pesticide Use and Lung Cancer Risk in the Korea National Cancer Center Community-Based Cohort Study: A Propensity Score Matching Analysis**

Byungmi Kim

*Byungmi Kim<sup>1</sup>, Eunyong Park<sup>1</sup>, Jinsun Kim<sup>1</sup>, Eunjung Park<sup>1</sup>, Jin-Kyoung Oh<sup>1</sup>, Minkyung Lim<sup>1</sup>*

*1. National Cancer Center Institute, Goyang, Korea (the Republic of).*

**Abstract:** Background: Pesticide use is associated with lung cancer, but the situation regarding lung cancer has not been clearly defined. We proposed a propensity score matching (PSM) analysis to evaluate relationship between pesticides use and risk of lung cancer in the Korea National Cancer Center community-based Cohort Study (KNCCCS). Methods: We evaluated use of pesticide and lung cancer cases in the KNCCCS, a prospective cohort study comprising 16,304 study participants from South Korea. Information about pesticide use and other factors was collected at enrollment (1993-2010). We compared four propensity-score-based approaches to confounding adjustment: matching, stratification, inverse probability treatment weighting (IPTW), and use of PS as a covariate. The differences in the baseline characteristics according to pesticide use were summarized using absolute standardized differences. Results: The hazard ratios between pesticide use and lung cancer varied from 3.04 (multiple model without PSM) to 5.40 (Stratification by 5 strata on the PSM). With all PSM methods, regression model adjusted as a continuous term with propensity score yielded estimated hazard ratios ranging from a low of 3.05 (95% CI: 1.27, 7.32) when IPTW was included to a high of 4.53 (95% CI: 2.61, 7.89). Results varied slightly by method, but direction and statistical significance remained the same. Conclusions: Our findings has strengthen the provide evidence for an association between pesticide use and lung cancer risk. Acknowledgements : This study has been financially supported by the National Cancer Center of Korea (grant numbers: NCC-1610650-1).

## **P02.3030. Hypertension, Cytokines, and Dioxin-Like Compounds in the Anniston Community Health Survey II**

Marian Pavuk

*Marian Pavuk<sup>1</sup>, Matt Cave<sup>2</sup>, Linda Birnbaum<sup>3</sup>*

- 1. ATSDR/CDC, Atlanta, GA, United States.*
- 2. University of Louisville, Louisville, KY, United States.*
- 3. NIEHS, Research Triangle Park, NC, United States.*

**Abstract:** Introduction: We conducted a follow-up study (ACHS II) of the Anniston Community Health Survey (ACHS 2005-7) in 2014. Participants were exposed to polychlorinated biphenyls (PCBs) concentrations that were about 3 times higher than in the general U.S. population and we observed significant associations between PCBs and hypertension. When endothelial cells are exposed to PCBs or other dioxin-like compounds in animal studies, inflammatory pathways may be activated and lead to increased expression of cytokines, which can contribute to the development of atherosclerosis and hypertension. Methods: Hypertension status was defined as being on antihypertensive medication or having a systolic/diastolic blood pressure greater than 140/90 mmHg; 262 (77.5%) of 338 participants were hypertensive. Cytokines measured included number of interleukins plasminogen activator inhibitor-1 (PAI-1), transforming growth factor beta 1 (TGF- $\beta$ 1), and tumor necrosis factor alpha (TNF $\alpha$ ) HADK2MAG-61K and HADK1MAG-61K bead arrays (EMD Millipore, Billerica, MA). The polychlorinated dibenzo-p-dioxins (PCDD), dibenzofurans (PCDF), and non-ortho PCBs were measured using high-resolution gas chromatography/high-resolution mass spectrometry and expressed as dioxin toxic equivalents (TEQs, pg/g lipid). Linear regression models adjusting for age, sex, BMI, family history of high blood pressure, and smoking status were applied. Results and Conclusion: We found statistically significant associations between PCDD TEQ and TNF $\alpha$ , PAI-1, and with TGF- $\beta$ 1 and non-ortho PCB TEQ and mono-ortho PCBs TEQ among hypertensive individuals. These findings suggest that these chemicals may be related to endothelial cell damage which increases production of inflammatory cytokines, the suppression of fibrinolysis, or downregulate AMP-activated protein kinase activation. These findings need to be replicated in other human cohorts exposed to dioxin-like chemicals.

## **P02.3040. Exposure to Asbestos and Colorectal Cancer: A Meta-Analysis**

Kyeongmin Kwak

*Kyeongmin Kwak<sup>1</sup>, Kyung Ehi Zoh<sup>2</sup>, Domyung Paek<sup>2</sup>*

*1. Department of Occupational and Environmental Medicine, Gachon University Gil Medical Center, Incheon, Korea (the Republic of).*

*2. Department of Public Health Science, Seoul National Universtiy, Seoul, Korea (the Republic of).*

**Abstract:** Background : The International Agency for Research on Cancer (IARC) concluded that there is limited evidence for a causal association between exposure to asbestos and colorectal cancer. This association, however, has been an old controversial. Objective : We performed a meta-analysis to quantitatively evaluate the association between exposure to asbestos and colorectal cancer. Methods : We searched for original articles in literature databases (PUBMED, EMBASE, Web of Science). Two authors independently reviewed articles and selected 42 cohort studies for meta-analysis Results : The overall pooled standardized mortality ratio (SMR) estimate for colorectal cancer was 1.11 (95% confidence interval, 1.00-1.24), with a high degree of heterogeneity (I2 = 66.1%). Our analysis of the studies that included only latent periods showed that the pooled SMR estimate was 1.08 (95% confidence interval, 0.93-1.24), with a high degree of heterogeneity (I2=71.0%). Conclusion : The overall pooled SMR of meta-analysis is statistically significant. However, the effect size was small, and SMR was not statistically significant when confined to the studies including latency. The evidence did not meet the established criteria for making a judgement for the existence of a causal association between asbestos and colorectal cancer.

**P02.3050. County-Level Radon and Incidence of Female Thyroid Cancer in Iowa, New Jersey, and Wisconsin, U.S.A.**

Jaymie Meliker

*Caroline Oakland<sup>2</sup>, Jaymie Meliker<sup>1</sup>*

*1. Stony Brook University, Stony Brook, NY, United States.*

*2. Hampton Bays High School, Hampton Bays, NY, United States.*

**Abstract:** Background: Few studies have investigated the association between radon and thyroid cancer despite the sensitivity of the thyroid gland to radiation. Our goal is to investigate the association between county-level radon and incidence of female thyroid cancer in the US States of Iowa, New Jersey, and Wisconsin. Methods: Thyroid cancer incidence data were provided by individual state cancer registries and span 1990-2013. Radon data come from a publicly available third-party database, AirChek, accessed in 2017. We tabulated the percent of radon above four picocuries per liter and the female thyroid cancer incidence rate in each county. Quantile maps were constructed, and an ordinary least-squares regression model was run using Geoda 1.10.0.8 (Chicago, IL, USA). Results: No association was observed between county-level radon and incidence of female thyroid cancer in any of the States: New Jersey ( $\beta = 0.06$ ,  $p = 0.23$ ); Iowa ( $\beta = -0.07$ ,  $p = 0.07$ ); or Wisconsin ( $\beta = -0.01$ ,  $p = 0.78$ ). A spatial regression model was considered, but the Moran's I of the residuals from each of the models was not significant, so no spatial term was required. Discussion: In this county-level ecological study across three different States in the US, we did not find an association between elevated radon and thyroid cancer incidence in women. While this ecologic study reports null findings, due to the ecologic fallacy, individual-level studies of this association may still be warranted.

## **P02.3060. Liquid Liver Biopsy in Residential Cohort Exposed to Polychlorinated Biphenyls Is Consistent with Steatohepatitis**

Matt Cave

*Matt Cave<sup>1</sup>, Christina Pinkston<sup>1</sup>, Shesh Rai<sup>1</sup>, Marian Pavuk<sup>2</sup>, Gleta Carswell<sup>3</sup>, Gail Nelson<sup>3</sup>, Brian Chorley<sup>3</sup>*

*1. University of Louisville, Louisville, KY, United States.*

*2. ATSDR/CDC, Atlanta, GA, United States.*

*3. US EPA, Research Triangle Park, NC, United States.*

**Abstract:** Introduction. Polychlorinated biphenyl (PCB) exposures have been associated with toxicant associated steatohepatitis (TASH) in animal models and suspected TASH in epidemiological studies including the Anniston Community Health Survey (ACHS). MicroRNAs (miRs) are non-coding RNAs that maintain cellular homeostasis and potentially mediate responses to environmental exposures. A 'liquid liver biopsy' was performed by serum miR profiling in PCB-exposed ACHS participants. Materials and Methods. ACHS participants, 152 (76 with and without suspected TASH), were evaluated. Suspected TASH was defined as serum cytokeratin 18 (CK18) M65>300 U/L and M30<200 U/L. Participants were stratified by sex. Sixty eight (68) targeted hepatotoxicity miRs were profiled in serum (Fireplex miRNA multiplex assay, Abcam). Serum adipocytokines and HOMA-IR were measured. Adjusted linear regression models examined relationships between the miRs and suspected TASH, CK18, PCBs, and adipocytokines. Ingenuity Pathway Analysis (IPA) was also performed. Results. Eight miRs were associated with suspected TASH. Four were upregulated (miR-22, -122, -320, and -375) and 4 were downregulated (miR -21, -92a, -223, and -410). Two miRs were associated with PCB exposures (let-7d and miR-181), including one which was also associated with increased CK18 M65 (let-7d). IPA demonstrated enrichment in pathways associated with liver steatosis, hyperplasia, decreased albumin, and HCC. Of the 8 miRs associated with suspected TASH, 4 miRs were also associated with IL-6, IL-8, PAI-1, adiponectin and resistin; while 3 miRs were also associated with HOMA-IR. Conclusions. 'Liquid liver biopsy' in subjects with suspected PCB-related TASH was consistent with steatohepatitis. Specifically, alterations in pathways related to steatosis, injury/death, inflammation, liver function, and hepatocarcinogenesis were detected. The results require histologic validation as well as confirmation in other cohorts.

**P02.3080. Environmental Exposure to Cadmium and Elevated Liver Enzymes in General Population in Republic of Korea**

**Abstract:** INTRODUCTION: Cadmium (Cd) is a well-known toxicant, but there is a lack of epidemiological studies that have been conducted to clarify the effect of environmental Cd exposures on abnormal liver function in general population. We aimed to examine the association between Cd levels in blood and elevation of liver enzymes in adults and adolescents, from national representative data. METHODS: We analyzed the nationally-representative and cross-sectional survey data from 8,533 adults and 3,347 adolescents in the Korean National Health and Nutrition Examination Survey 2010-2013 and 2016. The concentration of Cd in blood was classified as the quintile in both adults and adolescents. Abnormally elevated liver enzymes were defined as a ALT $\geq$ 40IU/L, AST $\geq$ 40IU/L, and GGT $\geq$ 30IU/L. We evaluated associations between blood Cd concentration and serum liver enzymes levels (ALT, AST, and GGT) by performing multivariable logistic regression analyses for the survey data adjusted for covariates: Age, sex, alcohol consumption, smoking status, obesity, physical activities, or socioeconomic status. RESULTS: In adults, exposure to the highest quintile of blood Cd had a significant association with abnormally high liver enzymes (OR, 2.09 [95% CI: 1.43, 3.05] for ALT; 1.94 [1.14, 3.28] for AST; 1.80 [1.15, 2.83] for GGT; all p-trends<0.05), comparing to the lowest. In adolescents, there was a significant association between exposure to the highest quintile of blood Cd and elevation of ALT (OR, 2.97 [95% CI: 1.01, 8.73]; p-trend<0.05), but no association in AST and GGT (2.07 [0.58, 7.40] for AST; 4.13 [0.65, 26.17] for GGT; all p-trends>0.05). CONCLUSIONS: This present study supports that the environmental Cd exposure may induce the elevation of liver enzymes in general population and it could be helpful to establish reliable regulation to Cd exposure for public health. ACKNOWLEDGEMENT: J.K. and E.P. contributed equally to this work.

## **P02.3090. Geographic Patterns in U.S. Lung Cancer Incidence by Histologic Type**

Denise Lewis

**Abstract:** Background: Geographic variation in U.S. lung cancer incidence overall and by histologic type has not been explored. Investigation of these patterns may inform etiologic hypotheses about environmental risk factors. Methods: Using North American Association of Central Cancer Registries (NAACCR) high quality state data, we calculated age-adjusted sex-specific lung cancer incidence rates for whites, overall and for microscopically-confirmed adenocarcinoma, squamous cell carcinoma, and small cell carcinoma cases by state and health service area. We investigated incidence patterns during 2004-2014 and trends from 2004-2009 to 2010-2014. Results: Cases from 43 states plus the District of Columbia were included. Total lung cancer incidence rates per 100,000 males were highest in Kentucky (104.6), Mississippi (94.1), and Arkansas (90.2). Female rates were highest in Kentucky (69.3), Delaware (60.0), and West Virginia (59.0). Rates for males and females were lowest in Utah. Lung cancer rates declined notably among males in California, Texas, and Hawaii and modestly in the southeast; female rates increased in Kentucky, Maine, New York, and Florida and declined in Texas, Arkansas and the west coast. Male adenocarcinoma rates remained high in the southeastern U.S. with elevated rates in North Dakota, South Dakota, Iowa, Nebraska, Iowa, and Pennsylvania. Female adenocarcinoma rates increased in New York, Connecticut, Massachusetts, New Jersey, Kentucky, Florida, and California. Rates of squamous cell carcinoma were stable, while small cell carcinoma rates declined among both males and females. Conclusions: This analysis reveals U.S. areas with high adenocarcinoma rates where smoking rates were not historically high. Analyses using locally-weighted and Poisson regression approaches will compare smoking-adjusted rates between regions. Insight into risk similarities and differences by refined geographic, demographic, and smoking characteristics will be presented.

Abstract: One of the main aims of the HEALS project is to unravel, through an exposomic approach, the development of metabolic diseases. The objective of the present study was to investigate the relationship between body burden from endocrine disrupting chemicals (EDCs) exposure (Holtcamp, 2012; La Merrill and Birnbaum, 2011) and the onset of overweight, obesity and diabetes, in view to promote preventive actions. Data was obtained from several pre-existing European cohorts (REPRO-PL, PI1, PI2, IMCA, SEASD, CCM, PHIME-CRO, PHIME-SI, G21, EPITeen, EDEN, CHISQ200 and MAAS). They were harmonised and cleaned to obtain a final dataset of 28,608 individuals. To replace missing values, a multiple imputation methodology was used. The EWAS analysis employed a survey-weighted logistic regression method with a Bonferroni correction to adjust the probability values and counteract the problem of multiple comparisons. As dependent variables, the health outcomes considered were overweight (BMI $\geq$ 25), obesity (BMI $\geq$ 30) and type-2 diabetes mellitus. As independent variables, 70 environmental assays and other demographic factors, at different periods of life were included. Obesity was found to be positively and significantly associated with PM10 (OR=1.174, p-value=0.005), NO<sub>2</sub> (1.276, 0.030), PCB118 (2.687, 0.026), zinc (1.098, 0.021) and several class of phthalates like MEHP (1.095, 0.026). A negative association was observed for some stressors like brominated diphenyl ether BDE153 (0.980, 0.001) and cadmium (0.868, 0.001). Comparable results were obtained for overweight and diabetes. Our EWAS analyses confirm potential association between multiple environmental factors and overweight, obesity and diabetes. Whether mechanisms underlying metabolic changes depend on adipocyte proliferation and differentiation, glucose homeostasis, insulin release or behaviour (traffic pollution may also lead to less physical activities and sedentary lifestyle) needs to be further investigated.

**P02.3110. Association between Concurrent Exposure to Dioxin and Mercury and Metabolic Syndrome in an Endemic Area in Taiwan**

*1. Department of Occupational medicine, Chimei medical center, Tainan, Taiwan.*

*2. Department of Environmental and Occupational Health, College of Medicine, National Cheng Kung University, Tainan, Taiwan.*

**Abstract:** Introduction: Both dioxin and mercury are related to the development of metabolic syndrome (MetS). However, studies on the effect of concurrent to dioxin and mercury on metabolic syndrome are limited. We conducted a study in Taiwan to evaluate the effect in an endemic area where resident were exposed to both polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs) and mercury released from a factory. Methods: We recruited participants from residents in the endemic area and defined serum PCDD/Fs levels  $\geq 20$  pg WHO98-TEQDF/g lipid and mercury levels  $> 20$  ppb as high exposure mercury levels. MetS was defined as meeting three of the following: fasting glucose  $\geq 100$  mg/dL or under treatment for diabetes, waist circumference  $\geq 90$  cm in men or  $\geq 80$  cm in women, triglycerides  $\geq 150$  mg/dL or under treatment for elevated triglycerides, high-density lipoprotein  $< 40$  mg/dL in men or  $< 50$  mg/dL in women, and blood pressures  $\geq 130/85$  mmHg or under treatment for hypertension. Uric acid  $\geq 7$  mg/dl was defined as high level. Results: In the 2758 participants, 785 patients of MetS were identified. We observed positive associations of both high dioxin level and high mercury level with MetS. After adjusting for sex, uric acid, and age, we found high dioxin levels (adjusted odds ratio [AOR] = 1.39, 95% confidence interval [CI]: 1.12-1.73), high mercury levels (AOR = 1.59, 95% CI: 1.14-2.23), older age (AOR = 2.81, 95% CI: 2.21-3.582 for 40-64 year and AOR = 4.57, 95% CI: 3.42-6.10 for age  $\geq 65$  year), and high uric acid levels (AOR = 2.31, 95% CI: 1.87-2.87) were independent predictors for MetS. Conclusions: Both exposures to PCDD/Fs and to mercury were associated with MetS, independent of age and uric acid.

## **P02.3130. Exposure to Electromagnetic Fields and the Risk of Brain Cancer**

James Gomes

*James Gomes<sup>1</sup>*

*1. Interdisciplinary School of Health Sciences, University of Ottawa, Ottawa, ON, Canada.*

Abstract: Electromagnetic fields (EMF) emitted by mobile phones, wireless devices, transmission towers and other sources are a cause for concern. The purpose of this study is to review the current data for exposure to EMF and known biological effects and evaluate the mechanistic possibility of the development of brain tumours, possibly through epigenetic modifications. Systematic review of literature was conducted using pre-determined criteria to collate the relevant literature. Scientific research suggests that EMF in contact with biological tissues is able to induce changes in cell cycle, cell death and alterations in protein and gene expression in laboratory studies. Other health effects including altered glucose metabolism, increased calcium flux, reduced cognitive function, melatonin disruption, alterations in DNA and brain tumours have been suggested. The current epidemiological data suggest a weak non-conclusive association between exposure to EMF primarily from mobile phones and brain cancers. Epidemiological studies also inconclusively suggest the development of acoustic neuroma, glioma, meningioma and ipsilateral use of mobile phones with a latency period of over 10 years from exposure to EMF. However, toxicology data from in-vivo and in-vitro studies indicates that the development of brain tumor is possible and plausible.

## **P02.3140. Association between Blood Lead Levels and Liver Fat Accumulation in Young Adults**

Alejandra Cantoral

*Alejandra Cantoral<sup>1</sup>, Karen E. Peterson<sup>2</sup>, Howard Hu<sup>3</sup>, Mauricio Hernández-Ávila<sup>4</sup>, Adrienne S. Ettinger<sup>5</sup>, Adriana Mercado<sup>1</sup>, Maritsa Solano<sup>1</sup>, Martha M. Téllez-Rojo<sup>1</sup>*

**Abstract:** Background: Recent evidence has linked lead exposure to Non-Alcoholic Fatty Liver Disease (NAFLD) as liver is a target organ and a repository of the metal. The aim of this study was to estimate the association between lead exposure during childhood and the amount of fat in the liver of Mexican young adults. Methods: This study includes 94 participants representing a subsample from the first birth cohort of the ELEMENT project started in 1994. Data include the historical venous blood lead measurements during childhood and the recent quantification of fat in the liver 22 years after the cohort started (2016). Four blood lead level (BLL) determinations were available from participants annually between 1 to 4 years of age; average of BLL was analyzed as continuous and as a categorical variable (>5 and >10 mcg/dL). Magnetic resonance imaging was used to quantify the percentage of fat in the liver. Models were adjusted for: birth weight, sex, SES, and current: Age, alcohol intake, smoking habits, energy intake, and BMI. Results: Participants ranged in age from 21 to 22 years; 53% were male. Median BLL in childhood was 7.5mcg/dL (IQR 5.8, 9.3), 86.3% presented lead values >5mcg/dL and 18.5% >10mg/dL. The median amount of fat in the liver was 1.5% (IQR 0.7-3.7); 19% presented with more than 5% of fat in the liver, considered as NAFLD. The adjusted linear regression models showed that for each extra unit of blood lead the percentage of fat in the liver increases 0.84% (CI 0.34, 1.32). Having BLL above 5 mcg/dL was not statistically significantly associated with fatty liver, but having more than 10 mcg/dL BLL during childhood was associated with higher liver fat (b= 6.18%, 95%CI 3.16, 9.21) compared to those below 10 mcg/dL. Conclusions: Lead exposure may lead to a higher percentage of fat accumulated in the liver during adulthood among those with elevated BLL in childhood. This association may be mediated through direct or indirect effects of lead on obesity.

## **P02.3141. Association between Fluoride Concentration in Public Water Supplies and Beneficial and Adverse Health Outcomes in England: An Ecological Study**

Abstract: The protective effect of community water fluoridation (CWF) on caries is established, but secular changes may modify its impact. Relationships with adverse health outcomes have also been alleged. We aimed to determine the association between concentrations of fluoride in public water supplies (PWS) and dental caries indicators, and certain adverse health-outcomes to monitor the health effects of CWF in England. We estimated exposure to CWF and PWS fluoride concentrations from national PWS monitoring data, using Geographic Information Systems and water supply boundaries. We categorised mean period exposure into <0.1, 0.1-<0.2, 0.2-<0.4, 0.4-<0.7, and  $\geq 0.7$ mg/l. We obtained area-level health outcome and confounder data from routine data sources. We used multivariable regression to determine the association between fluoride and health outcomes. The association between fluoride level and caries prevalence/severity varied by quintile of socioeconomic status (SES) ( $p < 0.001$  for interaction). Odds of caries, and of severe caries in five-year-olds, fell with increasing category of fluoride concentration in each quintile of SES ( $p < 0.001$  to  $p = 0.003$ ). There was a negative trend between increasing fluoride concentration and dental extractions ( $p < 0.001$ ). There were sporadic positive associations ( $p < 0.05$ ) between varying fluoride concentrations and Down's syndrome and kidney stones, but without evidence for a trend or threshold. There was a negative association with bladder cancer at the highest fluoride concentration. The association with hip fracture varied in direction by age ( $p < 0.001$ ), with a small positive association (RRs 1.03-1.05,  $p = 0.08$  or below) in adults aged 80 years+ at each fluoride concentration relative to <0.1mg/l. There was no strong evidence of an association with osteosarcoma. Exposure to fluoride in PWS appears highly protective of caries and caries extractions. Our findings did not provide clear evidence of an association with the adverse health outcomes.

## P02. Biomarkers of Exposure and Effects 2

### **P02.3150. German Environmental Specimen Bank: Characteristics of 24-H Urine Samples and Their Relevance for Human Biomonitoring - Experience from 20 Years of Trend Research**

André Conrad

*Dominik Lermen<sup>1</sup>, Martina Bartel-Steinbach<sup>1</sup>, Frederik Gwinner<sup>1</sup>, André Conrad<sup>2</sup>, Till Weber<sup>2</sup>, Maria Rüther<sup>2</sup>, Hagen von Briesen<sup>1</sup>, Marike Kolossa-Gehring<sup>2</sup>*

- 1. Fraunhofer Institute for Biomedical Engineering IBMT, Sulzbach, Germany.*
- 2. Federal Environment Agency, Berlin, Germany.*

**Abstract:** For documenting trends in human exposure, the German Environmental Specimen Bank (ESB) has been routinely collecting and archiving 24 h-urine samples from young adults at four sampling sites in Germany. In addition to pollutant concentrations, urinary creatinine (UC), specific gravity (SG), conductivity (CON) and total urine volume (UV<sub>tot</sub>) have been routinely recorded. It is known that the above-mentioned characteristics of 24 h- urine samples vary between individuals and over time and might affect data interpretation. To identify relevant differences and trends in these parameters, we analysed ESB data from 1997-2016 from 8,916 participants also with regard to the impact of sex, sampling site. Sampling sites do not substantially affect UV<sub>tot</sub>, UC, SG and CON. A significant increasing trend was revealed for UV<sub>tot</sub>. This increase is associated with UC, SG, and CON decreasing over time. Effects of normalization against these urine parameters were demonstrated for urinary Ca<sup>2+</sup> concentrations: From 1996-2016, Ca<sup>2+</sup> showed a significant decreasing trend over time. A normalization against UV<sub>tot</sub>, UC, or CON eliminated this trend. The known sex specific excretion for Ca<sup>2+</sup> is confirmed in this study. A normalization against UC, SG, or CON alleviated differences between sexes whereas a normalization against UV<sub>tot</sub> did not. To avoid misinterpretations in trend analysis and of sex specific excretion, the collection of 24-h urine samples and the calculation of the total daily excretion is recommended. Also if sampling is limited to spot or morning urine samples, the record of multiple urinary parameters should be considered for supporting data standardization. The suitability of these characterization may, however, vary by the analyte of interest, the study design, and the kind of urine sample taken. Funding by the German Ministry for the Environment (BMU) is gratefully acknowledged.

**P02.3160. Biomarker Assessment of Perfluoroalkyl Substance Exposure: Inter-Individual Differences Revealed by Use of Organic Anion-Inhibiting and Resin-Binding Drugs in a Community Setting**

Tony Fletcher

*Alan Ducatman<sup>2</sup>, Mike Luster<sup>2</sup>, Jianjun Zhang<sup>2</sup>, Tony Fletcher<sup>1</sup>*

- 1. Chemicals and Environmental Effects, Public Health England, Chilton, United Kingdom.*
- 2. Department of Occupational and Environmental Health, West Virginia University, Morgantown, WV, United States.*

**Abstract:** Background: Perfluoroalkyl substances (PFAS) are man-made, environmentally persistent organic compounds. Their long serum half-life in humans contrasts with findings from laboratory studies in rodents, and has been attributed to species differences in the activity of organic anion transporter (OAT)-directed renal tubular excretion or reabsorption of PFAS. Drugs which can affect excretion help in understanding underlying mechanisms for the long half-life, support causal inference in health hazard assessment and potentially offer a means to reduce community burdens of exposure. Methods: We determined the serum concentrations of four long chain serum PFAS concentrations among participants from the community-based C8 Health Project taking the uricosuric OAT-inhibitor probenecid (23 subjects), and the bile sequestrant anion exchange resin cholestyramine (36 subjects). These were compared to concentrations in a large adult population not taking these medications, after adjusting for age, gender, body mass index (BMI), calculated glomerular filtration rate (eGFR) and water-district of residence. Results: Those taking the resin cholestyramine had significantly lower serum PFAS concentrations, notably over 10-fold lower for perfluorooctane sulfonic acid (PFOS). Probenecid was associated with a modest, not statistically significant increases in serum PFAS concentrations. Conclusions: Our data confirm that cholestyramine increases excretion of PFAS, the first time demonstrated in community settings. They also suggest that probenecid-induced OAT inhibition in humans has little effect upon PFAS excretion. The findings point to the need for increased focus on non-renal physiology when considering PFAS excretion kinetics and a possible means to decrease PFOS contamination in humans. The strong effect of cholestyramine on serum PFAS also points to research needs on impact on serum PFAS of individual differences in gut reabsorption.

## **P02.3170. Total X-Ray Fluorescence for the Analysis of Multiple Elements in Dried Blood Spots**

Veronica Rodriguez Saldana

*Veronica Rodriguez Saldana<sup>1</sup>, Nil Basu<sup>1</sup>, Andrea Santa-Rios<sup>1</sup>*

*1. NATURAL RESOURCE SCIENCES , MCGILL UNIVERSITY , MONTREAL, QC, Canada.*

Abstract: Dried blood spots (DBS) have been hailed as a simple way to collect, transport and store biological (blood) samples for several analytical purposes. The technique is minimally invasive which makes it a cost-effective alternative to traditional venipuncture procedures. Despite this promise, there have been challenges in measuring analyte concentrations in DBS owing to small sample volumes, concentrations, and other factors. Total Reflection X-Ray Fluorescence (TXRF) may help overcome some these barriers, and thus the aim of this research was to develop and validate a novel method to perform a multi-element analysis (copper, zinc, selenium, iron, and lead) in DBS using TXRF. A TXRF-based method for multi-element analysis was validated by analyzing DBS from different human blood standard reference materials (SRM, Institut National de Santé Publique du Québec, INSPQ; n=7) with varying and known concentrations of elements. Percent recoveries, calculated by comparing DBS to known values, and coefficients of variation were analyzed for accuracy and precision. Stability of analyses was assessed by comparing results over 16 batch runs. The method was validated by quantifying the elements of interest in capillary whole blood and DBS collected from 49 healthy individuals. The limits of quantification of Cu, Fe, Pb, Se, and Zn were 5.08, 10.7, 3.45, 3.48, and 4.50 µg/L, respectively. The precision of the method was between 3.0-15.2% for the elements of interest. Percent recoveries for Cu, Zn, Se, and Pb using an entire 25 µL DBS of SRM were 106.7± 10%, 97.9± 11.9%, 105.5± 9.2%, and 80.8± 16.40%, respectively. These results show the potential of TXRF as an alternative analytical technique to quantify multiple elements in DBS samples. The results will be further explored with ICP-MS data.

## **P02.3180. Exposomic Biomarkers from the Residents in the Coastal Area of the Hebei Spirit Oil Spill**

Sungkyoon Kim

*Jangwoo Lee<sup>1</sup>, Myung-Sook Park<sup>2</sup>, Kyung-Hwa Choi<sup>2</sup>, Jongil Hur<sup>2</sup>, Hae-Kwan Cheong<sup>3</sup>, Sungkyoon Kim<sup>1</sup>*

- 1. Environmental Health Sciences, Seoul National University, Seoul, Korea (the Republic of).*
- 2. Taean Environmental Health Center, Taean, Chungcheongnam-do, Korea (the Republic of).*
- 3. Department of Social and Preventive Medicine, Sungkyunkwan University School of Medicine, Suwon, Korea (the Republic of).*

**Abstract:** Background/Aim Since the accident of Hebei Spirit oil spill in 2007, the repeated biological samples were collected from the Taean residents and their health status has been monitored; however, few chemicals were determined as exposure biomarkers. The aim of the present study is to identify exposomic markers of chemicals among the residents. Methods According to the oil-contaminated coastal area, exposure groups were assigned as high- and low-group. Six subjects from each provided urine samples at 2009, 2014, and 2016. Environmental chemicals in urine were screened with UPLC-qTOF-MS and determined by comparison with spectra of chemical standards and web-based chemical libraries. The levels of the analytes were expressed as the relative ratio with the average (1+2)-naphthol in urine. Results We compared the relative levels between the groups from all urine sample collected repeatedly. Among the high exposure group, (1+2)-naphthol was detected 1.5-fold more and their relative levels were 2.5-fold higher than control (low exposure group). Trans-, trans-muconic acid was detected more frequently in the low exposure group, but the relative concentrations were 1.2-fold higher in the high exposure group. N-Acetyl-S-(2,4-dimethylphenyl) -l-cysteine and N-Acetyl-S-(1-phenyl-2-hydroxy -ethyl) -l-cysteine showed higher detection frequency and 3-fold higher relative ratio in the high exposure group. Phthalate metabolites (mono-2-ethylhexyl phthalate), paraben, benzophenone-3, bisphenol F were also more in high exposure groups. However, the concentration levels of these compounds showed no association with any time span after the disaster and the variation of the levels was large. Conclusions The PAHs and VOCs metabolites seem related to the exposure area. Some environmental chemicals such as parabens and phthalates were also detected more in the high exposure group. In order to confirmation of their exposure sources, further studies are needed.

## **P02.3200. Characterization of Chemical Exposures in a Metropolitan Atlanta African American Birth Cohort Using Mass Spectrometry-Based Methods**

Priya D'Souza

*Priya D'Souza<sup>1</sup>, Parinya Panuwet<sup>1</sup>, Grace Lee<sup>1</sup>, Cierra L. Johnson<sup>1</sup>, Amanda Trotter<sup>1</sup>, Erin W. Williams<sup>1</sup>, Konstantsin Kartavenka<sup>1</sup>, Anne Dunlop<sup>2</sup>, P. Barry Ryan<sup>1</sup>, Dana Barr<sup>1</sup>*

*1. Environmental Health, Emory University, Atlanta, GA, United States.*

*2. Nell Hodgson Woodruff School of Nursing, Emory University, Atlanta, GA, United States.*

**Abstract:** Only a few population-based studies have been able to characterize environmental toxicant exposures in the United States. However, no such study has been conducted in the Deep South/Southeast, despite the fact that this region differs from others in climate, housing, population density, culture, and racial/ethnic composition. Little is known about how the pre- and post-natal exposomes of African American (AA) mother-infant pairs affect health and development because prospective studies examining these complex relationships are rare. We conducted a birth cohort study in a socioeconomically (SES) diverse pregnant AA population residing in metropolitan Atlanta. Using mass spectrometric methods, we characterized a portion of the exposome in a subset (N=56) of participants in order to understand the prevalence of exposures in this cohort. We measured concentrations of a broad suite of environmental toxicants in blood and urine samples including toxic heavy metals, brominated flame retardants, persistent pesticides, polychlorinated biphenyls, and poly- and perfluoroalkyl substances, as well as the metabolic forms of phenols, phthalates, parabens, nicotine, current-use pesticides, and polycyclic aromatic hydrocarbons. The metabolites of some phthalates, parabens, and pesticides were found to be significantly higher in this cohort than the general U.S. population, with lower SES participants tending to have higher levels. Our study is the first to characterize the environmental chemical exposome in an AA population in the Deep South/Southeast. The data suggest that environmental toxicant exposures are pervasive across metropolitan Atlanta and must be characterized further.

## **P02.3210. Exploration of Potential Biomarkers and Related Biological Pathways for P, P'-DDE Exposure in Maternal Serum**

Chisato Mori

*Chisato Mori<sup>1</sup>, Akifumi Eguchi<sup>1</sup>, Kenichi Sakurai<sup>1</sup>, Masahiro Watanabe<sup>1</sup>, Emiko Todaka<sup>1</sup>*

*1. Center for Preventive Medical Sciences, Chiba University, Chiba, Japan.*

Abstract: Dichlorodiphenyldichloroethylene (p, p'-DDE) have been associated with adverse human reproductive and fetal developmental measures or outcomes from their endocrine-disrupting effects. In this study, we aimed to identify the biological pathways and potential biomarkers of p, p'-DDE exposure in maternal serum using metabolomics platform. This study was approved by the Biomedical Research Ethics Committee of the Graduate School of Medicine, Chiba University. The Chiba study of Mother and Child Health (C-MACH) consisted of three hospital-based cohorts. A total of 433 women consented to participate in C-MACH. Due to a small number of current and previous smokers in this study, these participants were removed. Finally, the remaining 67 mothers were used for analysis. Serum levels of p, p'-DDE and metabolome were analyzed using the GC-NICI-qMS and HILIC-MS/MS, respectively. The median concentration of p, p'-DDE in maternal serum were 400 pg g<sup>-1</sup> wet wt. The levels of p, p'-DDE in maternal serum were slightly higher than that of PCB levels analyzed in our previous study (350 pg g<sup>-1</sup> wet wt.). We used the gradient boosting model with the metabolome profile to predict exposure levels of p, p'-DDE (first quartile [Q1] and fourth quartile [Q4]) for pregnant women. Areas under receiver operating characteristic curves, as measured by 3-fold cross validation (AUCCV = 0.840) and against an external test set (AUCEXT = 0.833), indicated the accurate classification of Q1 and Q4 population. In maternal serum, the valine, leucine and isoleucine biosynthesis, betaine metabolism, and glycine, serine and threonine metabolism (FDR <0.10), indicating disruption of metabolic pathways by p, p'-DDE exposure in pregnant women. Interestingly, PCB and p, p'-DDE levels in maternal serum were strongly correlated; however, related biological pathways were not overlapped. Thus, more detailed studies are needed to clarify the difference of biochemical changes resulting from PCB and p, p'-DDE exposure.

## **P02.3220. Maternal Biomarkers Relevant to Pregnancy and Birth Outcomes**

**Abstract:** Background: There is a need to elucidate specific mechanisms in-utero during pregnancy and to delineate the role of the biological markers. The expression of biological markers could help in understanding the effect of environmental exposures on pregnancy outcomes. This study aims to examine the role of biological biomarkers and the underlying mechanisms that may be associated with infant birth weights, gestational age and infant development in-utero. Methods: Electronic searches were conducted in relevant databases and all relevant papers were retrieved. Studies were selected if they evaluated maternal blood plasma/serum biomarkers proposed to influence adverse birth outcomes in the neonate. Data was extracted and odds ratios from each study and meta-analysis was conducted. Results: A total of 54 studies (35 for meta-analysis), including 43,702 women and collectively 50 biomarkers, were included in this study. The fixed effect point estimates for inflammation-related biomarkers were, 0.845(95%CI: 0.829-0.861,  $p < 0.0001$ ) for adverse birth outcomes and for hormone and growth factor-related biomarkers were 0.55(95%CI: 0.551-0.577,  $p = 0.0013$ ) for adverse birth outcomes. Pooled risk estimates for inflammation-related, hormone and growth factor-related biomarkers for preterm births were 0.845(95%CI: 0.829-0.861,  $p < 0.0001$ ) and 0.554(95%CI: 0.531-0.578,  $p < 0.0001$ ) respectively. Comparable risk estimates for delivery between 30 weeks and 37 weeks were 0.967(95%CI: 0.951-0.985,  $p < 0.0001$ ) and 0.759(95%CI: 0.759(0.657-0.861,  $p < 0.0001$ ) for inflammation related- and hormone and growth factor related- biomarkers respectively. Significant associations were seen between biomarkers and adverse birth outcomes with no apparent publication bias. Conclusions: The two subsets of plasma markers identified in this study (inflammation-related and growth factor/hormone-related) may serve as valuable tools in the investigation of maternal molecular mechanisms modulating adverse birth outcomes.

**P02.3230. Measuring the Responsome: Transcriptional Differences in mRNA Expression by Smoking Status and Obesity as Biomarkers for Human Sensitivity to Environmental Exposures**

Kristen Malecki

**Abstract:** The responsome is the collection of all physiological responses that can be influenced by the multitude of chemicals and environmental stimuli to which humans are exposed. While many studies have begun to examine DNA methylation as an upstream marker of altered gene expression, transcriptional biomarkers derived from whole blood mRNA may also provide important insights into human sensitivity to environmental exposures and differential response across populations. Obesity has been shown to alter physiological responses to air pollution and smoking but underlying biological mechanisms are largely unknown. Few studies have explored mechanisms by which obesity alters human sensitivity to environmental exposures. Overall study goals were to investigate whole blood gene expression in smokers and non-smokers to examine associations between cigarette smoke and changes in gene expression by obesity status and test for effect modification. Relative fold-change in mRNA expression levels of 84 genes were analyzed using a Toxicity and Stress PCR array among 21-54 year old adults (n=50). Data on smoking status was confirmed with urinary cotinine levels. Adjusted models included age, gender, white blood cell count and body-mass index (BMI). Six differentially expressed genes were associated with smoking after adjustments for covariates. Obesity was associated with 29 genes differentially expressed compared to non-obese. Significant smoking/obesity interactions were observed comparing for four DNA damage related genes (GADD45A, DDB2, RAD51 and P53), two oxidative stress genes (FTH1, TXN), two hypoxia response genes (BN1P3IL, ARNT), and one gene associated with unfolded protein response (ATF6B). Findings suggest transcriptional mRNA may provide opportunities for measuring the responsome. Implications for risk assessments and consideration of underlying phenotypes, like obesity, that may modulate sensitivity of vulnerable populations to environmental exposures will also be discussed.

## **P02.3240. From Exposure and Health to Action: Human Biomonitoring in Two Flemish Hotspot Areas**

Elly Den Hond

*Elly Den Hond<sup>1</sup>, Bart Bautmans<sup>2</sup>, Nico Bleux<sup>3</sup>, Sam De Craemer<sup>4</sup>, Annelies De Decker<sup>1</sup>, Caroline Teughels<sup>5</sup>, Guy Thys<sup>1</sup>, Liesbet Van Rooy<sup>2</sup>, Annette Vriens<sup>6</sup>, Vera Nelen<sup>1</sup>*

**Abstract:** Background In Flanders, the northern region in Belgium, there is long-term experience to perform human biomonitoring (HBM) studies in hotspot areas. The results of HBM campaigns can provide input for policy actions, both local and supra-local. Methods In Hoboken, children aged 1 to 12 years, living in the approximate neighbourhood of a metal refining plant, were sampled twice a year to measure blood lead through a capillary blood sample from 1978 to 2018. The industrial area 'Genk-Zuid' is the 3rd largest industrial area of Flanders. Both in 2010 and in 2016, biomarkers of exposure (heavy metals, PAHs, POPs) and biomarkers of effect (immune effects, DNA damage, hormonal disruption) were measured in 15-year old adolescents living close to 'Genk-Zuid', where air quality data showed frequent exceedances of the WHO guidelines. Results In Hoboken, results have raised awareness in the community, and have resulted in a working group with members of regional and local governments, industry, medical experts and citizens. The working group induces actions to lower emissions, remediate the area, and sensitize the general population for preventive actions. Individual results are a leverage to initiate personal guidance at different levels, i.e. prevention, action, treatment. In Genk-Zuid, the first HBM campaign in 2010 identified the major pollutants of concern, together with possible exposure routes, and paved the way to design a specific action plan. After 6 years of policy and action, the second HBM study in 2016 provided input for the evaluation and adjustment of the action plan. Throughout both campaigns, there was special attention for guidance and assistance in interpreting the individual results of the adolescents that participated in the study. Conclusion Human biomonitoring is a very powerful tool to initiate, apply and evaluate policy actions in local hotspot areas, both on an individual and a group level.

## **P02.3250. Levels of Contaminants in Human Populations in the Canadian Arctic**

Cheryl Khoury

Abstract: Levels of environmental contaminants, which are transported to the Arctic via air/water currents, have been shown to be elevated in northern populations, primarily Inuit. For more than 25 years, the Northern Contaminants Program (NCP) has funded research in response to concerns about exposure to contaminants from traditional, northern indigenous diets. Recently, NCP completed a human health assessment report, which provides a summary of current knowledge regarding contaminants and human health in northern Canada. Data from NCP funded studies were compiled to summarize levels of contaminants among Inuit children, pregnant mothers, women of childbearing age, and adult men and women. Data was also used to identify time trends and provide regional descriptive comparisons. This assessment found that concentrations of contaminants are higher in Inuit from northern Canada relative to the Canadian general population. This is primarily due to dietary exposure to contaminants from the consumption of certain country foods such as marine mammals. Inuit populations living in Nunavut and Nunavik, where these country foods are typically eaten more frequently or in larger amounts, had higher levels of contaminants. Time trend data show declining levels of organochlorines and metals (such as mercury and lead), by up to 80% and 60% respectively, in pregnant Inuit women from Nunavik (1992-2013). Despite this, levels remain elevated compared to the Canadian general population. Since the completion of the assessment new projects have been funded and these will also be highlighted. Strong time trend data are available for Nunavik; however more information is needed in other regions. New chemical groups have emerged in the Arctic. While human exposure data is still limited, data is being generated through new research. Additional conclusions, knowledge gaps and recommendations for future northern studies are detailed in the NCP human health assessment.

**P02.3260. Positive Association between Urinary Concentration of Lead, Cadmium and Subclinical Atherosclerosis in Adolescents and Young Adults**

Ta-Chen Su

*2. Institute of Occupational Medicine and Industrial Hygiene, National Taiwan University College of Public Health, Taipei, Taiwan.*

**Abstract:** Backgrounds: Urinary cadmium and lead have been associated with hypertension and cardiovascular diseases (CVD) in large population studies. However, there are still limited information linking exposure to heavy metal with subclinical atherosclerosis, particularly in young population. Methods: From a nationwide mass urine screening for renal health, conducted in 1992-2000 among school children 6 to 18 years of age in Taiwan, we recruited 789 subjects to participate in the cardiovascular health examination in 2006-2008. In the present study we evaluated the association between urinary levels of cadmium, lead, chromium, manganese, iron, nickel, copper, and zinc with carotid intima-media thickness (CIMT) in a cross-sectional analysis of 739 adolescents and young adults. Results: CIMT at all segments of carotid arteries significantly increased with the urinary lead and cadmium in a dose-response relationship after adjustment for major CVD risk factors. Multivariate logistic regression analysis showed that higher quartiles of urinary concentrations of lead and cadmium were associated with a higher risk of thicker CIMT (greater than 75th percentile). Compared to subjects with the lowest quartile (Q1) of urinary lead, the adjusted odds ratios (aORs) (95% confidence interval (CI)) for thicker CIMT among subjects with higher urinary lead were 2.56(1.35-4.85) for Q2, 3.76(2.00-7.08) for Q3, and 17.64(9.32-33.39) for subjects at Q4. Comparing those with lowest urinary cadmium, the corresponding aORs (95% CI) were 1.48(0.77-2.85) for Q2, 4.68(2.57-8.52) for Q3, and 13.58(7.34-25.13) for subjects at Q4. Conclusion: Higher urinary concentration of lead and cadmium was strongly associated with subclinical atherosclerosis in adolescents and young adults.

## **P02.3280. Environmental Exposures during Early-Life and Child Blood Pressure: An Exposome Approach**

**Abstract:** Introduction: There is growing evidence about fetal origins of hypertension but studies on the effect of environmental exposures during early-life are few and generally consider single exposures. This study aims to fill this gap using data collected from 6 European birth cohorts as part of the HELIX project. Methods: Blood pressure (BP) was measured among 1277 children at 7-10 years old using a standardized protocol. A wide range of prenatal (>90) and postnatal (>110) exposures were evaluated including the outdoor exposome (air pollution, built environment, meteorology, natural spaces, traffic, and noise), the individual exposome (biomarkers of exposure to chemicals), and lifestyle factors. Exposome-wide association study (ExWAS) using linear regression models adjusted for confounders and corrected for multiple testing was used. A variable selection method (DSA: Deletion, Substitution, Addition algorithm) was also applied. Results: ExWAS highlighted decreases in BP with markers of the built environment during pregnancy (e.g., IQR increase in facilities density [95% confidence interval]: -1.6mmHg [-2.5;-0.7]) and with child level of some organochlorine compounds (e.g., IQR increase in dichlorodiphenyldichloroethylene, DDE: -2.1mmHg [-2.9;-1.3]). The DSA selected the following exposures: 1) facilities density during pregnancy and maternal level of polychlorinated biphenyl 118 associated with lower BP, 2) maternal fish consumption, maternal level of bisphenol-A and outdoor temperature during pregnancy associated with higher BP, 3) child levels of DDE, hexachlorobenzene, and 2 phthalates metabolites, as outdoor temperature the day of examination, associated with lower BP, and 4) child levels of copper and perfluorooctanoate associated with lower BP. Conclusion: Quantifying the contribution of early-life environmental exposures to child BP is of critical importance since early intervention has the potential for significant benefits in reducing cardiovascular disease risk.

**P02.3290. HC-GC-MS Determination of the Inhalational Anesthetic Sevoflurane and its Specific Metabolite Hexafluoroisopropanol (HFIP) in Human Urine: Monitoring of Occupational Background Exposures**

Frederik Lessmann

*Frederik Lessmann<sup>1</sup>, Susann Finger<sup>1</sup>, Volker Harth<sup>1</sup>*

*1. Institute for Occupational and Maritime Medicine (ZfAM), University Medical Centre Hamburg-Eppendorf, Hamburg, Germany.*

Abstract: Today, sevoflurane is one of the most used inhalational anesthetics in human surgery, due to favourable pharmacological properties. However, teratogenic and neurotoxic effects resulting from chronic sevoflurane exposure are being discussed controversially. We present a sensitive human biomonitoring method for sevoflurane and its specific exposure biomarker hexafluoroisopropanol (HFIP) in human urine, to monitor occupational background exposures in operating room staff. Fresh urine samples are hydrolyzed at 37 °C in sealed headspace vials with beta-glucuronidase (HP-2 from *Helix pomatia*). Isoflurane is used as internal standard. After hydrolysis, samples are frozen at -18 °C for at least two hours. Samples are analyzed by static HS-GC-MS, and chromatographic separation is performed on a DB-1 column. Enzymatic hydrolysis was complete after three hours, and hydrolyzed samples were stable for at least 48 hours. Calibration was linear up to 2,000 µg/L and limits of quantification (S/N=10) for sevoflurane and HFIP were 0.3 and 3 µg/L, respectively. Precision and recovery in anonymously collected native urine samples of exposed patients (high exposure) for sevoflurane and HFIP were 5.3 % and 96 %, and 5.5 % and 93 %, respectively. Precision and recovery in spiked pooled urine samples (low level; around limit of quantification) were similar. Compared to previously published methods, the presented method stands out due to the simultaneous determination of both analytes, going along with excellent sensitivity. In spite of occupational health measures, such as waste anesthetic gas scavenging, and leakage checks of anesthetic delivery systems, sevoflurane exposure of operating room staff is presumably inevitable. Due to the excellent sensitivity for HFIP, and the simultaneous determination of both biomarkers, the presented method can be applied in future biomonitoring studies as a reliable exposure assessment tool to monitor occupational background exposures.

## **P02.3300. Maternal Swimming Pool Exposure during Pregnancy in Relation to Birth Outcomes and Cord Blood DNA Methylation among Private Well Users**

Lucas Salas

- 4. Department of Environmental Health, Rollins School of Public Health of Emory University, Atlanta, GA, United States.*

**Abstract:** Background: Swimming in pools during pregnancy may expose the fetus to water disinfection by-products (DBP). As yet, our understanding of the impacts on DBPs on the fetus is uncertain. Individuals with public water systems are typically exposed to DBPs through drinking and bathing, whereas those on private systems (such as wells), swimming in pools may be the primary exposure route. Objective: To investigate the effects of maternal swimming on birth outcomes and cord blood epigenetic changes in the New Hampshire Birth Cohort Study, a cohort of pregnancy women with households on private wells. Methods: Information about swimming in pools during pregnancy was obtained from 1,046 women via questionnaires. Swimming pool use and duration were modeled using linear regression with newborn weight, length, and head circumference (z-scores) and genome wide cord blood DNA methylation as the outcomes and with adjustment for potential confounders. Results: 16.5% of women reported swimming in a pool during pregnancy. Ever (vs. never) swimming was associated with larger head circumference (a z-score increase of 0.97 for first trimester and 0.73 for second or third trimester). Among swimmers, duration was inversely related to head circumference (-0.01 z-score per 10% increase in duration,  $p=0.02$ ). No clear associations were observed with birth weight or length. In a subset of the cohort with genome wide DNA methylation measurements, 18 CpG sites, mainly related to neurodevelopment, were associated with maternal swimming pool exposure ( $Q<0.1$ ). Conclusion: Our findings suggest swimming pool exposure may impact the developing fetus although longer-term studies are needed.

## **P02.3310. The Early-Life Exposome: Description and Patterns in Six European Countries**

Ibon Tamayo

*Ibon Tamayo<sup>1</sup>, Lea Maitre<sup>1</sup>, Cathrine Thomsen<sup>2</sup>, Mark Nieuwenhuijsen<sup>1</sup>, Valérie Siroux<sup>3</sup>, Leda Chatzi<sup>4</sup>, Remy Slama<sup>3</sup>, Martine Vrijheid<sup>1</sup>, Xavier Basagaña<sup>1</sup>*

Abstract: The "Exposome" is defined as the set of all environmental exposures that can influence health from conception onward and it has been advocated to better understand the role of environmental factors on multifactorial and chronic pathologies. Understanding what a typical exposome looks like, including the structure of correlations between and within groups of exposure, is important for multiple steps in exposome research, including the planning of which exposures to measure and the development of statistical analysis protocols. Here we aimed to describe the early-life exposome using data from the Human Early-Life Exposome (HELIX) project, in which 212 environmental exposures were measured in pregnant mothers and their children at 6-11 years in 6 European birth cohorts. Specifically, we focused on the correlations between multiple environmental exposures, their patterns and their variability across European regions and across time (pregnancy and childhood periods). The highest correlation was within water DBPs group (0.7) in pregnancy and within meteorology group (0.7) in childhood period. Between groups correlation was lower and all of them were less than 0.25. Ten principal components explained 45% of the total variance in the pregnancy exposome. In the childhood exposome, ten component explained 39%. In the correlation between mother and children, coefficients were high (> 0.6) for many of the exposures estimated for the residential or school address, such as atmospheric pollutants, green space, noise, traffic. Other built environment factors such as facility density had lower correlations ( $r < 0.40$ ). We characterized the early-life exposome in 6 European birth cohorts with over 200 environmental exposures measured, encompassed in 18 exposure groups, during two time periods using common protocols and methodologies. Our first descriptive analyses highlight several of the characteristics inherent in exposome data and the difficulties they pose for exposome-health analyses.

**P02.3320. Intrusion of Chlorinated Hydrocarbons and their Degradation Products from Contaminated Soil: Measurement of Indoor Air Quality and Biomonitoring by Analysis of End-Exhaled Air**

Paul Scheepers

*Paul T. Scheepers<sup>1</sup>, Martien H. Graumans<sup>1</sup>, Maurice van Dael<sup>1</sup>, Laurie de Werdt<sup>1</sup>, Nicole Pinckaers<sup>1</sup>, Rob B. Anzion<sup>1</sup>*

*1. Radboud Institute for Health Sciences, Radboud university medical center, Nijmegen, GLD, Netherlands.*

Abstract: A historic contamination of chlorinated hydrocarbons from a former dry cleaning shop caused a soil contamination. These chemicals and their degradation products intruded into a book shop. Indoor air was characterized and the uptake by shop personnel was studied by biomonitoring. The aim of this study was to determine indoor air quality and uptake of soil contaminants and their degradation products. Samples of indoor air were collected over one week in the warm and cold season. Indoor air was sampled using canisters. End-exhaled air was collected from a male and female employee before the shop opened and after closure time. Chlorinated hydrocarbons were analysed with TD-GC-MS. Tetrachloroethylene (PER), trichloroethylene (TRI) and their degradation products 1,1-dichloroethylene (1,1-DCE), 1,2-trans-dichloroethylene (1,2-tDCE), 1,2-cis-dichloroethylene (1,2-cDCE) and methylene chloride (MC) were detected in ambient air. The carcinogen vinyl chloride was not detected. PER was the prime contaminant with week average air levels ( $\pm$ sd) of  $805.2 \pm 598.6$  in June 2016 and  $1031 \pm 499.3$   $\mu\text{g}/\text{m}^3$  in December 2017. Levels of MC, 1,2-tDCE, 1,2-cDCE and TRI were detected at concentrations below  $2.3$   $\mu\text{g}/\text{m}^3$ . When the barometric pressure was  $<1000$  mbar all substances of interest were detected in end-exhaled air but not anymore at  $>1000$  mbar. For PER the mean concentrations in end-exhaled air on each of the five workdays ( $\pm$ sd) increased from  $26.0 \pm 3.6$  and  $22.2 \pm 8.0$  ng/L in the morning to  $52.6 \pm 15.5$  and  $63.6 \pm 12.7$  ng/L in the evening, for the male shop owner ( $p < 0.05$ ) and female cashier ( $p < 0.01$ ), respectively. For MC and 1,1-DCE this pattern was not observed. Accumulation over the workweek was observed for MC but not for 1,1-DCDE and PER. Intrusion of soil contamination resulted in enhanced indoor air concentrations of chlorinated hydrocarbons above current indoor air standards. For PER in end-exhaled air an increase over the workday was consistent but accumulation over the week was not observed.

**P02.3330. Direct Analysis of Conjugated Metabolites to Evaluate Ortho-Phenylphenol (OPP) Exposure in Human Urine**

Patrick Bélanger

*Patrick Bélanger<sup>1</sup>, René Bérubé<sup>1</sup>, Normand Fleury<sup>1</sup>*

*1. CTQ, inspq, Quebec, QC, Canada.*

Abstract: Ortho-Phenylphenol (OPP) has been widely used as a fungicide and preservative. Two facts: low dose studies have demonstrated a low toxicity in animals and humans but high dose exposure to this contaminant has toxic effects such bladder cancer. Thus far, monitoring of OPP exposure in the general population has been performed by measuring OPP after urine hydrolysis with the  $\beta$ -glucuronidase/arylsulfatase enzyme (mostly) and sometimes by the use of a mineral acid. We developed a sensitive, accurate and robust method using liquid chromatography-tandem mass spectrometry (LC-MS/MS) to specifically measure OPP metabolites excreted in human urine, the sulfate (OPP-S) and glucuronide (OPP-G) species. Comparative analysis of urine using a direct method and chemical hydrolysis method previously developed in our laboratory showed no significant difference in OPP concentrations. Moreover, a significant difference showed that underestimation of OPP level occurs when  $\beta$ -glucuronidase/arylsulfatase enzyme deconjugation is used. Then, different epidemiological studies may show different levels of exposure depending of methodological approach used.

## **P02.3340. Early-Life Environmental Exposure Determinants of Child Cognition and Mental Health**

**Abstract:** There is increase concerns over child behavioral problems due to changing environments. Children are typically exposed to a long list of industrial chemicals that are neurotoxic but also to beneficial environmental factors such as spending longer periods surrounded by green spaces. In HELIX, we systematically tested the associations of an extensive set of exposures measured during pregnancy and childhood in 1,301 mother-child pairs, including outdoor and urban factors, chemical pollutants, indoor air pollutants, lifestyle and social factors. Cognitive function, emotional and behavioral problems were assessed at 6-11 yrs through the Raven Test Score (fluid Intelligence) and the standardized parent reports of child behaviour checklist (CBCL). An agnostic exposome-wide analysis considering each exposure independently was applied to assess exposome-neurodevelopment associations. Initial analyses for behavioral problems identified one out of 92 prenatal exposures significantly associated and 4 out of 110 post-natal exposures after multiple testing correction. It included an increase in symptom incidence with maternal tobacco smoking (0.34 [0.19,0.48]), also observed with an increase in emotional problems (0.20 [0.06,0.34]). No prenatal exposures remained associated with cognition after correction. In the child's exposome, child organic food intake (1.33 [0.64, 2.02]) was associated with Raven score and healthy diet (KIDMED index) was related with decreased symptoms in behavioral problems (-0.13[-0.19,-0.07]) but indoor air pollution was related to increased symptoms. These preliminary findings showed beneficial associations of child lifestyle factors with cognitive and behavior outcomes but also raised particular concerns for smoking and indoor air pollutants. Further analyses with other cognitive and behavior domains and population stratification will give us a major picture of the exposome effects.

## **P02.3350. Daily Intakes of Phthalates among Japanese Children**

Shoji Nakayama

*Mai Takagi<sup>1</sup>, Tomohiko Isobe<sup>1</sup>, Miyuki Iwai-Shimada<sup>1</sup>, Shoji F. Nakayama<sup>1</sup>*

*1. National Institute for Environmental Studies, Japan, Tsukuba, Ibaraki, Japan.*

**Abstract:** [Background] Phthalates have been widely used as plasticizers primarily for polyvinyl chloride (PVCs) as well as solvents in consumer products. They are ubiquitously present in our surrounding environment. It has been found that the phthalates and their metabolites have effects on reproductive functions and allergic reactions. Children's exposure to phthalates is not well studied in Japan. The aim of this study was 1) to estimate daily intakes of phthalates among Japanese children and 2) to elucidate routes of exposure. [Methods] Preschool children at the age of 2-7 (n = 104) were recruited. Indoor dust and air (24 hours) samples were collected from their houses. Duplicate diets (one day) and 24-hour pooled urine were sampled. Indoor dust, air, and diet samples were analysed for phthalates (di(2-ethylhexyl) phthalate (DEHP), dibutyl phthalate (DBP) and butyl benzyl phthalate (BBzP)) by gas chromatography tandem mass spectrometry (GC-MS/MS). Urine samples were analysed for phthalate metabolites using liquid chromatography tandem mass spectrometry (LC-MS/MS). [Results] Medians of estimated daily intakes of DEHP, DBP (DnBP+DiBP), and BBzP were 2.9, 1.7, and 0.03 µg/kg/day, respectively. Ninety five percentile of those exposure were 9.6, 8.3, and 0.18 µg/kg/day, respectively. Daily intakes of DEHP and BBzP did not exceed the Japanese Tolerable Daily Intakes (TDIs). In contrast, 9.6% of children had daily DBP intakes beyond the Japanese TDI of 5 µg/kg/day. Urine MiBP levels highly correlated with DiBP concentrations in indoor air (r = 0.75), and moderately correlated with that in indoor dust (r = 0.60) and diet (r = 0.43), suggesting the major route of exposure to DiBP was indoor air. Little correlation was found between urine MEHP and DEHP in diet, indoor air and indoor dust. However, we found elevated DEHP concentrations in indoor dust (median: 1700 µg/g), indicating that the indoor dust can contribute to the DEHP exposure.

## **P02.3360. Lessons Learnt from the First Results of the French National Biomonitoring Program**

Clémence Fillol

*Clémence Fillol<sup>1</sup>, Alexis Balicco<sup>1</sup>, Clémentine Dereumeaux<sup>1</sup>, Amivi Oleko<sup>1</sup>, Loïc Rambaud<sup>1</sup>, Abdessatar Saoudi<sup>2</sup>, Romuald Tagne-Fotso<sup>1</sup>, Abdelkrim Zeghnoun<sup>2</sup>, Sébastien Denys<sup>1</sup>*

*2. DATA, Santé publique France, Saint Maurice Cedex, France, France.*

**Abstract:** The French biomonitoring program consists now of two distinct cross-sectional national biomonitoring surveys: A perinatal component based on a selection of pregnant women enrolled in the French Longitudinal Study since Childhood (Elfe), in 2011 and a general population survey (children and adults) coupled with health examinations and with a nutritional component: Environment, Health, Biomonitoring, physical Activity, Nutrition (Esteban), in the period 2014-2016. The results of the perinatal component of the national biomonitoring program describe the french women exposure in France in 2011 and give us the first trends for inorganics and organics pollutants comparatively with other countries. All these results are now available and reference values for this population of french pregnant women have been established. These results need to be confirmed by the results in general population (1104 children and 2503 adults) that will be available in Esteban study in 2018. In the presentation of this program, it will be proposed to explain the last results and the perspectives of the program as for example monitoring time trends in biomarkers levels, monitoring the impact of public health policies and regulations aiming to reduce environmental exposures to chemicals and challenges about the integration of prevention in our studies. With the experience of these first biomonitoring surveys in France, we will be able also to identify the public health issues that are emerging for future surveys.

## **P02.3370. Exposure to Polycyclic Aromatic Hydrocarbon in Women Living in the Chinese Cities of Baoding and Dalian Regions Revealed by Hair Analysis**

**Abstract:** Polycyclic aromatic hydrocarbons (PAH) are produced from incomplete combustion of organic matter and released as environmental contaminants from activities such as transports, wood combustion, coal-fired power plants. In numerous urban areas worldwide, the levels of PAH exposure are considered critical regarding public health issues. The possibility to detect PAH and PAH metabolites biologically incorporated in human hair was demonstrated and proposed as biomarkers of exposure. Nevertheless, the possibility to distinguish different levels of exposure between different populations is still needed to validate the relevance of hair analysis in epidemiological studies. In this work, hair samples were collected from 204 women from two cities in China based on one year Air Quality Index history from governmental data (Baoding as polluted city and Dalian less polluted city). 8 out of the 15 parent PAH and 7 out of the 56 metabolites analyzed in this study were detected in all the samples. The highest concentrations in hair were observed for phenanthrene (4.2 to 889 pg/mg) > fluoranthene (1.05 to 204 pg/mg) > pyrene (3.2 to 124 pg/mg) for parent PAH, and for 9-OH-fluorene (0.04 to 1.78 pg/mg) > 2-OH-naphthalene (0.68 to 811 pg/mg) > 1-OH-anthracene (0.24 to 10.9 pg/mg) for metabolites. 14 parent PAH and 15 metabolites presented a significantly higher concentration in the hair samples collected from Baoding, as compared to Dalian. The median concentration of parent PAH was from 1.5 to 2.8 times higher in the hair of the subjects from Baoding than in subjects from Dalian and that of PAH metabolites was from 1 to 2.3 times higher. The study of inter-chemical associations revealed similarities and differences between the two areas, suggesting common and different sources of exposure depending on PAHs respectively. The results confirmed the relevance of hair analysis to identify qualitative and quantitative differences in PAH exposure between populations from different areas.

## **P02.3380. A Review of Serum Perfluorooctanoic Acid (PFOA) Concentrations over a Four-Year Period**

Lee Blum

*Lee Blum<sup>1</sup>*

*1. NMS Labs, Willow Grove, PA, United States.*

Abstract: Perfluorooctanoic acid (PFOA) is a synthetic perfluorochemical used in the production of fluoropolymers. Although phased out from emission and product content by manufacturers in the U.S. since 2015, PFOA is a persistent chemical that remains in the environment. Exposures to the general population typically occur through drinking contaminated water or from using PFOA containing products. On occasion, our laboratory is asked to test serum samples for PFOA. A review of our data over the past 4 years (2014 - 2018) revealed 2711 serum/plasma samples tested from individuals with unknown PFOA exposures. These samples were assayed using HPLC separation with negative-ion electrospray tandem mass spectrometry (LC-MS/MS). The samples were prepared for analysis by adding an analyte specific isotope as an internal standard with subsequent protein precipitation. The analytical measurement range was 0.5 to 100 ng/mL. Of the 2711 samples tested, 29 were less than our reporting limit of 0.5 ng/mL. The average ( $\pm$  S.D.), median, range, and 95th percentile of the PFOA serum concentrations from these data were 28.6 ( $\pm$  268) ng/mL, 5.8 ng/mL, <0.5 - 8200 ng/mL, and 62 ng/mL, respectively. The range of ages for the individuals tested was 10 to 95 years, average of 59 ( $\pm$  15) years. The number of samples from males was 1282. Their serum PFOA levels averaged ( $\pm$  S.D.) 42.3 ( $\pm$  377) ng/mL with a range of <0.5 - 8200 ng/mL. The geomean, median, and 95th percentile for these men were 8.0 ng/mL, 7.0 ng/mL, 76 ng/mL, respectively. From the population data, there were 1402 samples from females. For these women, the average ( $\pm$  S.D.), geomean, median, range, and 95th percentile PFOA serum concentrations were 15.4 ( $\pm$  87.5) ng/mL, 5.5 ng/mL, 5.0 ng/mL, <0.5 - 2200 ng/mL, 47 ng/mL, respectively. These PFOA results generally appear to be higher than values observed in other studies of the U.S. population.

## **P02.3390. A Cross-Over Health Intervention Trial of Children Consuming an Organic Diet**

Konstantinos Makris

*Konstantinos C. Makris<sup>1</sup>, Corina Konstantinou<sup>1</sup>, Solon Ioannou<sup>1</sup>*

**Abstract:** Introduction: The effectiveness of a systematic organic diet in improving key parameters of health in human studies has not been well studied. The objective of this study was to determine the intervention effectiveness of an organic diet in significantly reducing urinary pesticide metabolite concentrations and concomitantly affecting biomarkers of inflammation and oxidative stress in children. Methods: A 2 x 2 cluster-randomised cross-over trial at subject level study was designed for healthy children (n=150, 11-12 years old) from families historically consuming a conventional diet (>80% of weekly diet). The study period consisted of a 40-day conventional diet arm and a 40-day organic diet arm. Diaries were used to record the consumed diet and extent of compliance. A total of five morning urine voids samples per child in select time points of both conventional and organic phases were collected. Select metabolites of neonicotinoid/pyrethroid pesticides were monitored in children's urine using tandem mass spectrometry. Biomarkers of oxidative stress/inflammation and creatinine were measured in urine (isoprostane 8-iso-PGF2a and 8-OHdG) using immunoassay kits. Linear mixed-effects models of the biomarkers of effect were constructed to evaluate the main effects of organic diet and biomarker of exposure to pesticides accounting for both between- and within-subject variability. Results: The effect of organic diet on the biomarkers of oxidative stress/inflammation accounting for known confounders will be presented. Conclusions: To the best of our knowledge, this is the first time that the concomitant assessment of biomarkers of effect (oxidative stress/inflammation) along with biomarkers of exposure to pesticides in children systematically consuming an organic diet has been performed.

## **P02.3410. The Use of Dried Blood Spots for Mercury Assessment in Population-Based Research**

Andrea Santa-Rios

**Abstract:** Dried blood spots (DBS) represent an alternative and minimally invasive method for classical venous blood sampling especially in field-based research since there is no need for specialized equipment, cold-chain handling, and phlebotomists. There is a growing number of studies studying the use of DBS to assess exposure to Methylmercury (MeHg) and Total Mercury (THg) using samples collected under controlled laboratory conditions, but the method has not yet been validated under field-based research. The present study aims to validate the use of DBS as a tool for mercury assessment in populations with different levels of exposure to mercury compounds. Here we explored a number of factors in two field-based studies: A) DBS samples and field blanks were collected in an Artisanal and Small-Scale Gold Mine (ASGM) area in Colombia (n=55); and b) paired DBS-blood samples were obtained from e-waste workers (n=20) in Ghana and a set of DBS were created with the whole blood under laboratory conditions. In all cases, three DBS punches of 3mm ( $\approx 18\mu\text{l}$ ), blank paper, and  $18\mu\text{l}$  of whole blood were acid digested and analyzed for MeHg and THg. Focusing on the e-waste workers, MeHg concentrations were mean=  $1.07 \pm 0.60 \mu\text{g/L}$  in whole blood and DBS, and mean=  $0.14 \pm 0.06 \mu\text{g/L}$  for the blanks samples. The results showed no significant differences between DBS created in the laboratory and collected in the field (paired t-test  $p=0.685$ ) and their respective blanks (paired t-test  $p=0.536$ ). Paired DBS-blood samples showed a high correlation ( $r^2=0.95$ ). We are currently analyzing the ASGM samples for MeHg and all the samples for THg mercury. The results are expected to increase our understanding of DBS as a potentially novel means to assess mercury exposure. Which could have immediate applications in established programs such as newborn screening and demographic health surveys

## **P02.3420. The Establishment of Simultaneous Analysis Method for Metabolites of Phthalates and Dinch in Human Urine by UHPLC-MS / MS**

Sungmin Kim

Abstract: Phthalates are plasticizers that are used to make plastics flexible, and are widely used in medical devices, toys, building materials, plastic products, various chemical products. There are many kinds of phthalates such as DBP, DEHP, DINP, DIDP. and It has been reported that it causes endocrine disruption. For this reason, the United States, the European Union and other countries around the world began to regulate the use of phthalates. Phthalates have been regulated and replaced with new compounds such as DINCH. DINCH is now widely used worldwide and is expected to have wide exposure to humans. It is also unclear how DINCH will affect the human body. Therefore, it is important to grasp the degree of exposure of phthalates and DINCH in humans in advance. This study is to establish a method for simultaneous analysis of metabolites of urinary phthalate and DINCH by UHPLC-MS/MS to determine the degree of exposure of phthalates and DINCH. The analysis substances are total 23 metabolites including 20 metabolites of phthalate and MINCH, OH-MINCH, and MEHTP which are metabolites of DINCH and DEHTP. Urine was prepared using enzymatic deconjugation with the  $\beta$ -glucuronidase followed by solid-phase extraction. The samples were analyzed by UHPLC-MS/MS. To verify accuracy and precision, spikes the standard solution into each 7 urine samples to a final concentration of 0.5, 5, 50 ng/mL, and validated for 3 days. As a result of confirming accuracy and precision, the accuracy was 82-109%(intra-day) and 85-105%(intra-day). Precision was less than 20%. The detection limit were 0.14-0.66 ng/mL and the linearity of the calibration curve was appropriate. This method can be used to investigate the human exposure of phthalates and DINCH.

## **P02.3430. Metabolomics of Childhood Exposure to Perfluorooctanoic Acid: A Cross-Sectional Study**

Joseph Braun

*Samantha L. Kingsley<sup>1</sup>, Douglas I. Walker<sup>2</sup>, Aimin Chen<sup>3</sup>, Antonia Calafat<sup>4</sup>, Bruce Lanphear<sup>5</sup>, Kimberly Yolton<sup>6</sup>, Kurt Pennell<sup>7</sup>, Joseph M. Braun<sup>1</sup>*

**Abstract:** Background: Exposure to perfluorooctanoic acid (PFOA), a synthetic and persistent chemical used in commercial and industrial processes, is associated with reduced birth weight, increased adiposity, dyslipidemia, and liver injury. These diverse toxic effects suggest that PFOA elicits multiple biological responses. Identifying the metabolic changes induced by PFOA exposure could enhance our understanding of potential biological mechanisms. Study Objective: To identify metabolic changes associated with serum PFOA concentrations in 8-year old children using a metabolome-wide association study (MWAS). Methods: Using venous blood samples collected from 120 8-year old children in Cincinnati, OH, we quantified serum PFOA concentrations and performed untargeted metabolomic profiling by liquid chromatography-high-resolution mass spectrometry. We evaluated metabolic variations associated with PFOA concentrations using linear regression and false discovery rate (FDR) <20%. We identified associated metabolites with the METLIN mass spectral database and metabolic pathway enrichment analysis. Results: At FDR<20%, higher serum PFOA concentrations were associated with 239 detected chemical signals; 130 were positive associations. Initial annotation of the mass spectral data showed that both endogenous metabolites and perfluoroalkyl chemicals were associated with PFOA exposure. Using untargeted metabolomics, we detected PFOA, perfluorooctanesulfonic acid, and additional signals consistent with fluorinated chemicals. Biological alterations associated with PFOA concentrations included keratin sulfate degradation and metabolism of purine, caffeine, Vitamin E, linoleate, urea cycle/amino groups, glyoxylate, dicarboxylate, and galactose, consistent with changes to immunological, oxidative stress and catabolism pathways. Conclusions: This is the first study to perform a MWAS with PFOA exposure in children and provides new insights into the biological responses associated with PFOA exposure.

**Abstract:** Background: The Household Air Pollution and Intervention Network (HAPIN) trial aims to demonstrate the effects of a liquefied petroleum gas (LPG) intervention on health in biomass using homes across four low- and middle-income countries (LMICs). We report results from cross validation of a high performance liquid chromatography with fluorescence detection (HPLC-FLD) method for the measurement of polycyclic aromatic hydrocarbon (PAH) metabolites in human urine including 1-hydroxypyrene (1OHP) and 2-naphthol (2NAP) as biomarkers of PAH exposure, at the HAPIN trial site in India. Methods: A HPLC-FLD method was developed to analyze a set of 25 split human urine samples sent from the Laboratory of Exposure Assessment and Development for Environmental Research (LEADER) at Emory University, Atlanta, USA. LEADER measured the same analytes using liquid chromatography-tandem mass spectrometry (LC-MSMS). Results of these two analytical methods were compared using Bland-Altman plots. Subsequent urine samples collected from pregnant mothers (n=40) and adult women (n=40) during the pilot activities of HAPIN trial were also analyzed by HPLC-FLD. Results: The limits of detection for 2NAP and 1OHP were 0.52ng/ml and 0.65ng/ml, respectively. Bland-Altman analysis showed large 95% confidence levels for 2NAP with a bias of about 2.98ng/ml with HPLC-FLD data being lower than LC-MSMS data at higher concentrations. For 1OHP, the 95% confidence levels were fairly small with much smaller bias of 0.17ng/ml and better agreement when outliers were excluded. The mean concentrations ( $\mu\text{g/g}$  creatinine) and range of 2NAP and 1OHP in pregnant mothers were 25.8 (2.3-110.8) and 6.2 (0.25-24.1), respectively, and in adult women, 26.4 (0.94-82.7) and 3.1 (0.27-14.3), respectively. Conclusion: The HPLC-FLD method can serve as a cost-effective and reliable analytical method to measure 1OHP and 2NAP (with additional refinement) in an LMIC laboratory and support biomarker activities of the HAPIN trial.

## **P02.3450. Age-Period-Cohort Analysis of Blood Lead in the United States, 1976-2016**

Yutaka Aoki

*Yutaka Aoki*<sup>1</sup>

*1. National Center for Health Statistics, Centers for Disease Control and Prevention, Hyattsville, MD, United States.*

**Abstract:** Background: Blood lead in the U.S. population has decreased substantially since 1970 owing to exposure reducing measures. Historically the trajectory of blood lead over time has been described in terms of secular-trend in age-specific geometric means. To our knowledge, an alternative analytical approach, age-period-cohort analysis, has not been applied to nationally representative data. Objective: To investigate how age, period, and birth cohort are associated with lead body burden in the U.S. population. Methods: Data on 76,066 individuals, who took part in National Health and Nutrition Examination Surveys (NHANES) conducted in 1976-1980, 1988-1994, and 1999-2016 and were born since 1900, were used. The main outcome was erythrocyte lead. Geometric means by birth decade and 5-year age groups were described graphically. Using log-linear regression, erythrocyte lead was modeled as a function of age, period, and/or birth cohort variables, entered as either discrete or continuous (transformed and/or as natural spline). Results: A descriptive plot of erythrocyte lead over age by birth decade cohort showed that, after the 1976-1980 period with relatively small differences by birth decade and age, erythrocyte lead had a marked decrease, which is consistent with the decrease previously documented in blood lead. Preliminary regression-based analysis revealed that during 1976-1980 erythrocyte lead varied by birth decade and already was decreasing over calendar time at an age-dependent rate. For instance, erythrocyte lead of participants aged 50 in 1976 decreased by 39.4% (95% confidence interval 32.0%-42.8%) 4 years later. Conclusions: The age-period-cohort analysis was useful in visualizing and uncovering certain previously unrecognized patterns in time-related changes in lead body burden. Further analyses are underway, using data from 1988-1994 and 1999-2016, for which a continued decrease in blood lead over time has been documented.

**P02.3460. Environmental Tobacco Smoke Exposure among Children at 7 Years of Age in Japan: Associated Factors and Urinary Cotinine Levels**

Machiko Minatoya

*Machiko Minatoya<sup>1</sup>, Atsuko Araki<sup>1</sup>, Chihiro Miyashita<sup>1</sup>, Tamiko Ikeno<sup>1</sup>, Sumitaka Kobayashi<sup>1</sup>, Reiko Kishi<sup>1</sup>*

*1. Center for Environmental and Health Sciences, Hokkaido University, Sapporo, Hokkaido, Japan.*

**Abstract:** Abstract Introduction: Child exposure to environmental tobacco smoking (ETS) remains as a major issue, with adverse health consequences such as obesity, neurobehavioral disorders. This study aimed to identify associations between ETS exposures of children at 7 years of age defined by parent-reports and child urinary cotinine levels and sociodemographic factors. Methods: Child exposure to ETS was assessed by urinary cotinine levels and parent-reported questionnaire in 1440 children in the prospective birth cohort study. The questionnaire included parental smoking habit, and sociodemographic variables. Definition of ETS was if either/both parent(s) smoked or urinary cotinine level > LOQ (1.30 ng/ml). The associations were examined by logistic regression. Results: Based on parent-reports and the urinary cotinine levels, 55.5% and 34.2% of children were exposed to ETS at 7 years of age. Among 492 children with quantifiable urinary cotinine levels, the geometric mean was 6.77 ng/ml (minimum = 1.30 and maximum = 325.5, respectively). Children from younger parents, lower parental education levels, lower annual family income and maternal cotinine levels at 3rd trimester of pregnancy had higher odds ratio (OR)s for ETS and for quantifiable urinary cotinine levels. Past ETS exposure was also associated with increased ORs. Even mothers do not smoke beside children, log<sub>10</sub> transformed urinary cotinine level significantly increased ( $\beta=0.49$ , 95% CI: 0.37, 0.62). Smoking more than 10 cigarettes/day by either of both mothers and fathers significantly increased urinary cotinine levels of children. Conclusions: ETS exposure was confirmed in 34% of children by urinary cotinine measurements, and is still an unresolved public health issue in Japan. Not smoking beside their children was not enough for them to avoid ETS. The health professional should put more emphasis to the parents on the importance of controlling the ETS exposure of their children.

**P02.3470. Decrease in Urinary Biomarkers of Di-2-Ethylhexyl Phthalate (DEHP) Metabolites and Oxidative Stress in Children after Withdrawal from Exposure to 2011 Taiwan's DEHP-Tainted Food Scandal: A 44-Month Follow-Up**

Ming-Tsang Wu

*Ming-Tsang Wu*<sup>1</sup>

*1. Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung city, Taiwan.*

**Abstract:** Background: A major health scandal involving phthalate-tainted foodstuffs occurred in Taiwan in 2011. The presence of a clear relationship between phthalate toxicity in children and oxidative stress as the main cause is still under question. This study investigated temporal changes of oxidative stress by monitoring two urinary oxidative stress biomarkers: 8-OHdG and MDA with urinary DEHP oxidative metabolites during 44 months following withdrawal of the tainted food. Methods: Two cohorts were established. One cohort was collected from a Phthalates Clinic for Children in southern Taiwan between May 31 and June 17, 2011, in Kaohsiung Medical University Hospital (KMU cohort). That cohort of children was followed up at 2, 6, and 44 months. The other cohort was collected from a nationwide health survey conducted by Taiwan's National Health Research Institutes (NHRI) for people potentially exposed to phthalate-tainted foods post-scandal, between August 2012 and January 2013 (NHRI cohort). The current study only included children 10 years old and younger who had provided enough urine for the final analysis, including urinary DEHP oxidative metabolites, 8-OHdG and MDA concentrations. Results: In the KMU cohort, estimates of DEHP daily intake and the two biomarkers of oxidative stress levels (urinary 8-OHdG and MDA) were found to have decreased to nadir by the follow up at six months. These low points were maintained at follow-up of 44 months and were similar to those found for the NHRI cohort whose urine samples were collected post scandal at 15 to 18 months. Generalized linear mixed models by generalized estimating equation (GEE) in KMU cohort found that levels of predicted values of 8-OHdG and MDA at visit of 2, 6, and 44 months, were significantly lower than at baseline visit ( $p < 0.001$ ). Conclusions: We conclude that oxidative stress can be reversed in children exposed to phthalate-tainted foodstuffs after withdrawal from the sources of exposure till 44-months follow up.

**P02.3480. Associations between Urinary Organophosphorous Flame Retardant Metabolites and Measures of Adiposity in the U.S. General Population: NHANES 2013-2014**

Lesliam Quiros-Alcala

*Meleah D. Boyle<sup>1</sup>, Jessie Buckley<sup>2</sup>, Lesliam Quiros-Alcala<sup>1</sup>*

*1. Maryland Institute for Applied Environmental Health, University of Maryland, Rockville, MD, United States.*

*2. Departments of Environmental Health & Engineering and Epidemiology, Johns Hopkins University, Baltimore, MD, United States.*

Abstract: Organophosphorous flame retardants (OPFRs) are synthetic chemicals commonly added to many consumer products, including furniture, electronics, and building materials. Emerging in vitro and in vivo animal studies suggest that OPFRs may alter metabolism and affect obesity risk via effects on sex and thyroid hormones, peroxisome-proliferator-activated receptors, and oxidative stress. In this study, we examined cross-sectional associations between five urinary OPFR metabolites [diphenyl phosphate(DPhP), Bis(1,3-dichloro-2-propyl) phosphate(BDCPP), Bis(2-chloroethyl) phosphate(BCEtP), Dibutyl phosphate(DBuP), and Bis(1-chloro-2-propyl) phosphate(BCPP)] with adiposity measures [obesity, body mass index(BMI) and waist circumference(WC)] among 1351 adults aged 20-80 years and 638 children aged 6-19 years participating in the US National Health and Nutrition Examination Survey. We estimated associations in multivariable logistic and linear regression models, adjusted for age, gender, race/ethnicity, urinary creatinine, smoking, diet, physical activity, and screen time. For adults, we observed increased prevalence odds of being obese vs. normal weight among those with detectable BCPP levels (adjusted Prevalence Odds Ratio (aPOR):1.78,95% Confidence Interval, CI:1.20,2.64) as well as increased prevalence odds of having a high vs. normal WC (aPOR:1.65,CI:1.17,2.32). Among children, we observed a significant inverse association between log<sub>10</sub>-DBuP concentrations and the prevalence odds of being obese vs. normal weight (aPOR:0.41, CI:0.22,0.77). Similar trends were observed with BMI z-scores ( $\beta$ :-0.36,p=0.02) and WC ( $\beta$ :-3.14,p=0.03). Overall, OPFR associations did not differ by gender among adults or children. Findings suggest that exposure to certain OPFRs may be differentially associated with body size among adults and children. Future prospective studies are needed to confirm these findings and take into account potential windows of susceptibility, including the prenatal period.

## **P02.3490. Pb-Adulterated Turmeric: A Growing Problem**

Whitney Cowell

*Whitney Cowell<sup>1</sup>, Wendy Heiger-Bernays<sup>2</sup>*

*1. Environmental Medicine and Public Health, Mount Sinai Icahn School of Medicine, New York, NY, United States.*

*2. Department of Environmental Health Sciences, Boston University School of Public Health, Boston, MA, United States.*

Abstract: Spice adulteration remains a global public health issue. Evidence indicates that contamination of turmeric with lead (Pb) is a growing problem in the United States and likely other countries. Since 2011, over 20 brands of ground turmeric and curry powder sold in the United States have been recalled due to contamination with Pb. For example, in 2016 approximately 337,000 pounds of curry powder was recalled in Florida and New York due excessive concentrations of Pb. Several international media outlets have cited adulteration of turmeric with Pb chromate, which is vibrant yellow and closely matches the natural color of turmeric, as an ongoing problem. India and Bangladesh are major exporters of the global turmeric supply and in 2010 the Times of India reported over 100 bags of turmeric contaminated with Pb chromate were found at a spice manufacturing plant. Turmeric use is increasing, including as a natural dye in cheeses, cereals, mustards, margarines and packaged foods intended for children, such as Kraft Macaroni and Cheese<sup>®</sup>. Since 2011, multiple childhood Pb poisoning cases attributable to consumption of contaminated turmeric have been reported by Departments of Public Health. Furthermore, turmeric has become popular due to its natural anti-inflammatory properties; it is currently the best-selling dietary supplement in the United States. Turmeric-based beverages are increasingly available at mainstream grocery stores; after dehydrating several of these beverages, we found a 12-ounce juice may contain up to 18 grams of turmeric powder. The FDA has not established a recommended maximum level for Pb in spices and since spices are typically excluded from general U.S. population dietary surveys, accurate estimates of intake are challenging. The evidence suggests turmeric is adulterated with Pb to enhance its weight, color, or both. Researchers and public health officials should be aware of this growing source of dietary Pb exposure.

**P02.3500. Urine Collection Methods for Non-Toilet-Trained Children in Biological Monitoring Studies: Validation of a Disposable Diaper for Characterization of Tebuconazole Exposure**

Paul Scheepers

*Arné Oerlemans<sup>1</sup>, Maurice H. van Dael<sup>1</sup>, Roel Vermeulen<sup>2</sup>, Frans Russel<sup>1</sup>, Paul T. Scheepers<sup>1</sup>*

*1. Radboudumc, Nijmegen, Netherlands.*

*2. IRAS, Utrecht, Netherlands.*

Abstract: Young children differ from adults in their exposure and susceptibility to environmental chemicals (e.g. pesticides) because of various factors such as behavior, diet and physiology. Furthermore, children of 0-3 yr. old are rarely included in biomonitoring studies and thus the information on the exposure of chemical compounds of this group is very limited. Their heightened vulnerability to environmental stressors makes it important to obtain appropriate urine samples for exposure characterization. However, collecting urine from non-toilet-trained children has been shown to be methodologically and practically challenging. The aim of this study was to examine and evaluate different urine collection methods for non-toilet-trained children that could be applied in a non-clinical setting. Four urine collection approaches were tested, including a disposable diaper, a urine bag, a collection pad containing a hydroscopic polymer, and the clean catch. The success rate, defined as the percentage of total attempts which were suitable for urine analysis, and the user rating on a 0-10 scale (0=inconvenient, 10=convenient) of each method were evaluated. The success rates were 67%, 21%, 17% and 4% for the disposable diaper, urine bag, collection pad and clean catch, respectively. The average user ratings on a 0-10 scale were 9.0, 4.7, 7.3 and 2.5, respectively. Subsequently, the best rated method, the disposable polyacrylate diaper was tested with hydroxy-tebuconazole as an exposure biomarker for the fungicide tebuconazole and creatinine for urine density adjustment. Recoveries were on average 107% for hydroxy-tebuconazole and 87% for creatinine. Precisions for both analytes were between 3% and 10%. Based on this study, we consider the disposable diaper as a suitable method for urine collection of non-toilet-trained children for biomonitoring of tebuconazole. This study can serve as a basis to extent this method other substances of interest.

Abstract: Dried blood spots (DBS) are a novel matrix for cardiovascular biomarkers and are lower in cost and participant burden than venous blood collection. The objective of this study is to determine if the analysis of whole blood extracted from DBS via finger stick yields comparable biomarker values as the analysis of venous blood plasma. This study was conducted as a series of validation studies for biomarkers of interest in the Household Air Pollution Intervention Network Trial (HAPIN). Finger-stick DBS and venous-drawn blood were collected for the pre-intervention, formative research among 40 women in Rwanda, Peru, and Guatemala (n=120 paired samples). The biomarkers of interest are indicators of cardiovascular distress and inflammation: C-reactive protein (CRP), vascular adhesion molecule-1 (VCAM-1), and intercellular adhesion molecule-1 (ICAM-1). Existing paired samples at Emory University, USA, were used to develop the analytic methods. We used the MESO Scale Diagnostics MESO SQ QuickPlex 20 with MSD Vascular Injury Panels, which include capture antibodies on four spot, 96-well plates. We utilized an incubation and extraction procedure with a PBS Tween 20 0.05% eluate to liquefy the DBS. We will compare biomarker concentrations for the two collection/analytic methods via correlation and Bland-Altman plots. Preliminary results utilizing samples from the methods development indicate high correlation between paired samples for CRP (r=0.98) and moderate to low correlation for ICAM-1 (r=0.28) and VCAM-1 (r=0.17). Our results suggest that DBS may offer reliable measures of inflammation, particularly for CRP. Further analyses will inform the choice of biomarkers for the main trial by incorporating samples as collected, stored, and transported in the variable environments of the HAPIN locations. The use of DBS to measure biomarkers could have important implications for large field studies by including populations where venous blood collection may not be feasible.

## **P02.3520. The Value of Population Cohorts and Biobank Resources to Address Environmental Health Issues: The Cartagene Platform**

Nolwenn Noise!

**Abstract:** Chronic diseases result from a combination of individual genetic predisposition and exposure to environmental risk factors. The joint assessment of exposure and disease outcome is the key to accelerate breakthroughs in environmental health research. The selection of reliable and unbiased indicators are necessary to carry out high quality research but remains a big challenge. Large population cohorts and biobanks can provide high quality data for the assessment of both exposure and health effects. The CARTaGENE (CaG) cohort is the largest prospective health study in Québec. Since 2007, CaG recruited 43,000 participants, aged 40-69 years at baseline. CaG is characterized by a wealth of collected data on each participant: health questionnaire (lifestyle, mental health, etc.), physical measures (blood pressure, spirometry, electrocardiogram, etc.), food frequency questionnaire, residential and occupational histories, biochemical measures (eg. lipids, glycated hemoglobin, creatinine), and genotyping data. The CaG biobank contains biosamples (blood, plasma, urine, etc.) for more than 30,000 participants. These biosamples allow for the measurements of additional biomarkers (exposure or effect) for specific purposes. CaG databases are linked to administrative health databases which are of great value to inform about health care use and, along with prospective follow-up questionnaires, enable to collect data on a continuous manner to identify temporal variations. CaG is fully integrated in the Canadian Partnership for Tomorrow Project, which represents 300,000 participants and more than 150,000 biological samples available for health research. CaG was created to support the scientific community in identifying the determinants of chronic diseases of environmental and/or genetic origin. Longitudinal population cohort such as CaG offers very powerful tools for environmental epidemiology studies.

## P02. Risk Assessment and Policy 2

### P02.3530. Stochastic Modeling of Exposure to Chemicals in Consumer Products

Olivier Jolliet

*3. Office of Research and Development, United States Environmental Protection Agency, Research Triangle Park, NC, United States.*

Abstract: Recently, increasing attention has been paid to the near-field human exposure to chemicals in consumer products. To characterize these exposures, we first used the Stochastic Human Exposure and Dose Simulation Model (SHEDS) to generate the number of users and the mean chemical used per user for a simulated US population of 25,000 persons for 9700 chemical-consumer product combinations. We then estimated the product intake fraction - the fraction of chemical taken in - using a modified USEtox model to determine direct transfer fractions and cumulative fraction taken in by various receptors. These direct transfer fractions were calculated for these 9700 product-chemical combinations by 7 underlying models, including skin surface layer, object surface layer, article interior, indoor air, food contact material, pesticide and direct environmental emission. We then multiply the PiF by the chemical mass in products to determine the total intake dose, focusing on 34 chemicals monitored in the National Health and Nutrition Examination Survey (NHANES). The average population dose accounting for both users and non-users intakes ranges from 8.2E-8 to 3.1 mg/kg-d and is dominated by user contributions. The dose received by the users and by the average population can differ by several orders of magnitude. For example, for benzyl butyl phthalate the doses for direct user and average population are 394 and 0.036 mg/kg-d, respectively, indicating that this chemical is only in products used by 0.01% of the population. In contrast, the methylparaben doses for direct user and average population are 13.3 and 3.1 mg/kg-d, respectively, indicating that methylparaben is in products widely used (23%) in the population. For all 34 chemicals, the mean inferred dose from NHANES biomonitoring data ranges from 2.29E-8 to 126 mg/kg-d, similar to our estimated average population doses, the model tending to overestimate doses, pointing at the need to consider chemical prevalence in further studies.

## **P02.3550. Spatiotemporal Augmented Representation of Indoor Air Quality as a Tool for Decision Making**

Nastaran Arfaei

**Abstract:** A growing body of research points to the effects of indoor air quality (IAQ) on health and cognitive performance. IAQ measurements allow for the evaluation of indoor environments, and new sensor technology has made measurement more accessible. However, effective decision making for improvement of these environments is only possible through an understanding of the spatiotemporal distribution of these elements indoors. We designed an augmented reality (AR) system that takes real time air quality data from multiple sensors and creates a spatial map of these conditions. The program interpolates between the data points and creates a real-time three-dimensional heatmap that represents the concentration of air quality indicators. This map is projected on the physical environment through an AR application. This overlaid map can be seen through a digital device such as android tablet, cell phone or through Microsoft HoloLens (an AR headset). Users can toggle between various environmental factors such as CO<sub>2</sub>, particulate matter, humidity and temperature with the use of a virtual button. This novel system has the ability to make invisible environmental exposures visible through AR, which has implications for building design/operation, space use and occupant behaviors.

## **P02.3570. Effects of High Intensity Local Exposure of a 10 Ghz-Electromagnetic Field on Glial Activity in Rat Brain**

Hiroshi Masuda

*Hiroshi Masuda<sup>1</sup>, Itsuki Kageyama<sup>1</sup>, Tatsuya Ishitake<sup>1</sup>, Akimasa Hirata<sup>2</sup>, Sachiko Kodera<sup>2</sup>, Takuji Arima<sup>3</sup>, Yujiro Kushiyama<sup>3</sup>, Yoshitaka Morimatsu<sup>1</sup>*

*2. Nagoya Institute of Technology, Nagoya, Japan.*

*3. Tokyo University of Agriculture and Technology, Tokyo, Japan.*

**Abstract:** The possibility of radio-frequency electromagnetic fields (RF-EMF) of mobile phones to cause any adverse health effects on the brain is a subject of numerous studies and publications. Our previous studies have shown that no changes in microcirculatory parameters such as blood-brain barrier and leukocyte behaviors in pial microcirculation were found in the rat brain locally exposed to 1439 MHz EMF even at 2.0 W/kg of brain averaged specific absorption rate (BASAR). On the contrary, several recent studies reported that glial cells activated, indicating inflammation level, after the exposure to RF-EMF under non-thermal exposure conditions. However, the intensity level of RF-EMF exposure, which can occur the activation of glial cells, is still arguable. Therefore, it was necessary to define the intensity of local brain exposure to RF-EMF which affects the activation of glial cells. The aim of the present study was to investigate a threshold of the local exposure intensity of RF-EMF for the glial cells activation. Male Sprague-Dawley rats (8-9 weeks old) were used in this experiment. The rats were anesthetized with isoflurane (inhalation). The head of each animal was fixed in the stereotaxic apparatus and locally exposed to 10 GHz RF-EMF for 18 min using a monopole antenna. The field intensity was adjusted to make 0 to 2207 W/kg of averaged SAR in target tissue area. The two types of glial cells, microglia and astrocyte were observed 24 hours after the exposure using immunohistochemistry. As results, obvious morphological difference between sham-exposed and exposed animals were found in microglial cells. The RF-EMF exposure changed their morphology of ramified phase into those of ameboid phase under the high intensity exposure conditions. In contrast, there was no difference in astrocyte between two exposed groups even the same intensity level. We are now investigating the threshold intensity of RF-EMF for the microglial activity and expect to show it in the meeting.

## **P02.3580. Estimates of Exposure to Chemical Threat Agent Surrogates in the United States, 2012**

Dulaney Wilson

*Dulaney A. Wilson<sup>1</sup>, Kit Simpson<sup>1</sup>, Valerie Durkalski-Mauldin<sup>1</sup>, Erik Svendsen<sup>1</sup>*

*1. Medical University of South Carolina, Charleston, SC, United States.*

**Abstract:** The development of effective medical countermeasures against chemical threat agents is a priority. Limited civilian exposure to such agents limits our ability to develop effective countermeasures for humans. We propose to use the unintended exposure to agents similar to chemical threat agents as surrogates in order to describe the estimated national incidence of emergency department (ED) visits and hospitalizations for such agents in the U.S. National incidence estimates for 2012 were derived from the de-identified Healthcare Cost and Utilization Project (HCUP) National Inpatient Sample (NIS) dataset and the National Emergency Department Sample (NEDS). Visits for exposure to chemical threat agent surrogates were defined using International Classification of Diseases, 9th edition; Clinical Modification (ICD-9-CM) codes for specified (e.g. nitrogen oxides, chlorine, hydrocyanic acid) and unspecified irritant gas exposures as well as unintentional poisoning by organophosphates, fumigants and medicinal bromine. Frequency of visits was described. In 2012, there were ~31 million ED and 7.1 million inpatient (IP) visits in the HCUP data; when weighted these visits reflect 134 million ED and 36 million IP visits in the U.S. The estimated incidences of any toxic gas exposure were 96.7 ED and 75.8 IP per 100,000 visits. With regard to specific exposures, the estimated incidences for unspecified gas exposure were 39.8 ED/43.9 IP; for other specified gas exposure, 32.6 ED/17.6 IP; for nitrogen oxide exposure, 24.1 ED/14.9 IP; for hydrocyanic acid exposure, 5.3 ED/2.6 IP; and for chlorine exposures, 1.3 ED/0.4 IP per 100,000 visits. In general, the ED visit incidence was higher than IP visits with the exception of visits for an unspecified gas exposure although the magnitude differed by specific exposure. The incidence of ED and IP visits for chemical threat surrogates appears to be sufficient to inform prospective comparative studies of medical countermeasures to these threats.

**P02.3590. The Federal Research Action Plan on Recycled Tire Crumb Used on Synthetic Turf Playing Fields and Playgrounds: Tire Crumb Rubber Characterization and Exposure Study Recruitment Strategy and Questionnaire**

Kelsey Benson

Abstract: The U.S. Federal Research Action Plan on Recycled Tire Crumb Used on Playing Fields and Playgrounds is a multi-agency collaborative effort with several research activities. CDC/ATSDR and EPA conducted a tire crumb characterization study and a pilot-scale exposure characterization study. The tire crumb characterization study aimed to analyze tire crumb rubber for a variety of chemicals and to characterize field use patterns and maintenance procedures using a structured questionnaire. The objective of the exposure characterization study was to characterize activity patterns for synthetic field users and measure exposure to chemicals during activities at synthetic turf fields. For the tire crumb characterization study, a convenience sampling approach was used for recruitment of potential fields. A total of 306 community field owners/managers were contacted for potential participation, and sample collection was completed at 40 synthetic turf fields, including 21 community fields and 19 military installation fields. A questionnaire was administered to each field/facility owner/manager to gather information about their synthetic turf field facilities, field users, operations, and maintenance. For the exposure characterization study, participant recruitment was conducted at three fields (two outdoor and one indoor) that participated in the tire crumb characterization study. In-person recruitment was conducted Monday through Thursday immediately prior to, during, and after field activities. The study included 32 participants who provided responses about their frequency, duration, and types of activities at athletic fields, as well as information about hygiene, and other potential exposure information. This presentation will describe recruitment strategies and criteria for field selection and field users, field/facility operations and maintenance that could affect potential exposures and questionnaire results from the exposure characterization study.

## **P02.3610. Relative Oral Bioavailability of Cobalt and Nickel in Residential Soil and Dust Affected by Metal Grinding Operations**

Caroline Ring

*Caroline L. Ring<sup>1</sup>, Mina Suh<sup>1</sup>, Stan Casteel<sup>2</sup>, Margaret Dunsmore<sup>2</sup>, Ann Verwiel<sup>1</sup>, Deborah Proctor<sup>1</sup>*

*1. ToxStrategies, Inc., Austin, TX, United States.*

*2. College of Veterinary Medicine, University of Missouri, Columbia, MO, United States.*

**Abstract:** In vivo relative bioavailability (RBA) assessments were conducted for cobalt (Co) and nickel (Ni), in baghouse dust, surface dust, and soil collected in a neighborhood near a metal forge. Baghouse dust contained 8,000 mg/kg Co and 45,000 mg/kg Ni; surface dust contained 970 mg/kg Co and 6000 mg/kg Ni; and soil contained 53 mg/kg Co and 330 mg/kg Ni. Test materials (baghouse dust, surface dust, and soil) and reference materials-cobalt chloride (CoCl<sub>2</sub>) and nickel sulfate (NiSO<sub>4</sub>)-were administered daily for 14 or 21 days, twice daily, to juvenile swine. Daily intake doses for Co were  $\leq 229$  mg/kg-day and for Ni  $\leq 1,419$  mg/kg-day. Concentrations of Co and Ni were measured in liver, kidneys, femur, and duodenum; 24-hour urinary excretion of each metal was also measured. Multiple linear regression modeling was performed for tissue concentration or urinary excretion vs. dose in each material, with weighting as inverse variance in each dose group. RBA for each test material was estimated as the ratio of best-fit slopes for test material and reference material. Models were evaluated on residual heteroscedasticity and goodness-of-fit metrics. Uncertainty in RBA was estimated from uncertainty in the best-fit slopes. Cobalt RBA in baghouse dust was 8.7% (90% CI: 2.6%-15%); in surface dust, 12% (90% CI: 0.47%-23%); and in soil, 3.8% (90% CI: -6.0%-14%). Nickel RBA in baghouse dust was 4.5% (-57% to 53%); in surface dust, 2.4% (90% CI: -9.6% to 14%); and in soil, 20% (90% CI: -78% to 106%). Nickel RBA estimates were highly uncertain in soil and baghouse dust, likely because the soluble reference material (NiSO<sub>4</sub>) was poorly absorbed. These data demonstrate that cobalt and nickel in soil and dust affected by metal alloys are resistant to absorption. This study provides useful information to be incorporated into site-specific human health risk assessments.

## **P02.3620. Emerging Regulatory Issues and Exposure Assessment of Furfuryl Alcohol**

Jamie Schenk

*Jamie E. Schenk<sup>1</sup>, Ankur Singhal<sup>1</sup>, Carolyn Scrafford<sup>1</sup>, Renee Kalmes<sup>1</sup>*

*1. Exponent, Inc., Oakland, CA, United States.*

Abstract: Furfuryl alcohol (FFA) is a flavoring agent used in a variety of consumer food products, including coffee, tea, cocoa, milk products, nuts, breads, popcorn, and cask-stored alcoholic beverages. FFA in food products is typically produced as a byproduct of thermal processing or aging of alcoholic beverages. A National Toxicology Program (NTP) study in 1999 indicated that there may be "some" evidence of carcinogenic activity in male F344/N rats and male B6C3F1 mice through the inhalation route. The ingestion route was not evaluated. As such, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) concluded in 2000 that there is "No safety concern at current levels of intake when used as a flavoring agent." A panel on Food Additives, Flavorings, processing Aids and Materials in Contact with Food also came to the same conclusion. However, the U.S. Environmental Protection Agency (EPA) classified FFA as "likely to be a human carcinogen", followed by California's Office for Environmental Health Hazard Assessment (OEHHA) adding FFA to its Proposition 65 list as a carcinogen. There are several limitations of the NTP study, yet this study serves as the backbone of several regulations. The NTP study did not evaluate ingestion, yet conclusions based on inhalation are being used to inform policy that primarily pertains to ingestion. Additionally, neoplastic changes were only observed at the highest doses, which may have exceeded the maximum tolerated dose. We suggest that a linear extrapolation to estimate exposures at human-relevant doses may not be appropriate for FFA. Therefore, we propose an alternate non-linear model to more accurately estimate low dose exposures, with examples of exposure assessments for certain food products.

## **P02.3650. Fluoride Levels in Mexican Foods and Beverages**

Lynda Luna Villa

*Lynda C. Luna Villa<sup>1</sup>, Alejandra Cantoral<sup>2</sup>, Andrés A. Mantilla Rodríguez<sup>3</sup>, Frank Lippert<sup>3</sup>, Karen E. Peterson<sup>4</sup>, Howard Hu<sup>5</sup>, Adriana Mercado<sup>1</sup>, Martha M. Téllez-Rojo<sup>1</sup>, E. A. Martinez-Mier<sup>3</sup>*

- 4. Departments of Nutritional Sciences, University of Michigan School of Public Health, Ann Arbor, MI, United States.*
- 5. Dalla Lana School of Public Health , University of Toronto, Toronto , ON, Canada.*

**Abstract:** **INTRODUCTION** The sources of fluoride exposure for the Mexicans are foods, beverages, fluoridated salt and naturally fluoridated water. The main objective of this study was to estimate the concentration of fluoride in foods and beverages most frequently consumed in Mexico; in addition, their fluoride content was compared to data available from the United States (US) and the United Kingdom (UK). **METHODOLOGY** From the Health and Nutrition Survey 2012 we identified 182 foods and beverages and purchased in the biggest supermarkets chains and local markets in Mexico City. Samples were analyzed for fluoride content at least in duplicate to account for variability at the Oral Health Research Institute, Indiana University School of Dentistry, using a modification of the hexamethyldisiloxane microdiffusion method. **RESULTS** We tested 166 foods and 16 beverages, classified into 14 food groups to compare with their US and UK counterparts, and finding among them a very wide range of values. Foods with the lowest and highest fluoride content were vegetable shortening (0.24µg/100g) and fried/baked pork rinds (1465.40µg/100g), respectively. The food groups with lowest and highest content were eggs (2.32µg/100g) and seafood (371.29µg/100g), respectively. When estimating the amount of fluoride ingested per portion size, the lowest values corresponded to eggs and the highest to fast food. When comparing between countries, meats and sausages, cereals, fast food, sweets and cakes, fruits, dairy products, legumes and seafood from Mexico, presented higher fluoride contents than similar foods from the US or the UK. Drinks and eggs from the US exhibited the highest fluoride contents, while this was the case for pasta, soups and vegetables from the UK. **CONCLUSION** The majority of tested Mexican foods and beverages contained higher fluoride contents than their US and UK counterparts. The Mexican data generated in this study will be useful to facilitate the monitoring of the intake in the population.

## **P02.3660. Hexabromocyclododecane Transfer from Flame-Retarded Curtains to Attached Dust**

Takeo Sakurai

Abstract: Dust is potentially important as a medium of exposure to low- and semi-volatile organic compounds in the indoor environment. To examine the transfer of hexabromocyclododecane (HBCD) isomers to dust on the surface of flame-retarded curtains, a series of 196-day laboratory experiments were conducted using two types of curtains and attached dusts. Concurrently, the physicochemical properties (vapor pressure, water solubility, and octanol-water partition coefficient) of the HBCD isomers were measured because knowledge of the isomer-specific values of these properties is still limited. HBCD isomers migrated from curtains to dust on a timescale of about 20-50 days. The composition of HBCD, dominated by  $\gamma$ -HBCD in the curtains, was dominated by  $\alpha$ -HBCD in the post-experiment dusts, probably because of the higher vapor pressure of  $\alpha$ -HBCD compared to  $\gamma$ -HBCD. The initial HBCD contents of the two curtains were comparable, but the concentrations and profiles of HBCD isomers in the post-experiment dusts differed markedly, probably because differences between the texture, surface finishing of the treated fabrics, or both affected HBCD transfer to the attached dust. We hypothesized that HBCD vapor from the curtain was sorbed onto dust surface and then gradually diffused into the interior of the dust particles, and a mechanistic model based on this hypothesis qualitatively reproduced the observed HBCD concentrations in house dust.

**P02.3670. Identification of Cells Involved in the Induction of TNF- $\alpha$  Expression by Methylmercury in the Mouse Brain and Its Molecular Mechanisms**

Gi-Wook Hwang

*Takayuki Hoshi<sup>1</sup>, Takashi Toyama<sup>1</sup>, Akira Naganuma<sup>1</sup>, Gi-Wook Hwang<sup>1</sup>*

*1. Graduate School of Pharmaceutical Sciences, Tohoku University, Sendai, Miyagi, Japan.*

Abstract: Methylmercury is an environmental pollutant that causes neurotoxicity. Recently, we found that tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ; inflammatory cytokine) is selectively induced in the brain of mice administered methylmercury. Although TNF- $\alpha$  may be involved in the neurotoxicity caused by methylmercury, the mechanisms involved in the induction of TNF- $\alpha$  expression by methylmercury are unknown. In this study, we aimed to identify cells involved in the induction of TNF- $\alpha$  expression by methylmercury in mice brain, to elucidate the underlying molecular mechanisms. Seven days after subcutaneous injection of C57BL6 mice with methylmercuric chloride (25 mg/kg), TNF- $\alpha$  mRNA levels were determined in the brain tissues by in situ hybridization. We found that TNF- $\alpha$  was hardly expressed in the saline-administered group, whereas TNF- $\alpha$ -expressing cells were observed in the whole area of the brain in the methylmercury-treated group. It was reported that astrocytes and microglial cells are involved in the induction of TNF- $\alpha$  expression. Therefore, we performed immunostaining using antibodies specific for GFAP or IBA1, which are specifically expressed in astrocytes and microglial cells, respectively. The TNF- $\alpha$ -expressing cells did not overlap with the GFAP-positive cells, but with the IBA1-positive cells. The results suggest that microglial cells are mainly involved in the induction of TNF- $\alpha$  expression by methylmercury in the mouse brain. In addition, methylmercury induced TNF- $\alpha$  expression in mouse microglial cell line BV2. MAP kinases such as JNK, ERK, and p38 are known to be involved in the induction of TNF- $\alpha$  expression in microglial cells. We found that all three MAP kinases were phosphorylated by methylmercury treatment. Moreover, when the cells were pretreated with specific inhibitors, only the p38 inhibitor suppressed the induction of TNF- $\alpha$  expression by methylmercury. These results indicate that methylmercury may induce TNF- $\alpha$  expression via activation of p38 in microglial cells.

## **P02.3680. Mapping Soil Heavy Metal Levels in England and Wales for Application in Public Health**

Annalisa Sheehan

*Annalisa Sheehan<sup>1</sup>, Brandon Parkes<sup>1</sup>, Anna Hansell<sup>1</sup>, John Gulliver<sup>1</sup>, Susan Hodgson<sup>1</sup>*

*1. Epidemiology & Biostatistics, Imperial College London, London, United Kingdom.*

**Abstract:** Background/Aim: Heavy metals, especially Lead (Pb), Cadmium (Cd) and metalloid Arsenic (As), have known health impacts. Using extensive soil sampling data from the British Geological Survey (BGS) we aimed to generate reliable soil metal concentration surfaces, with accompanying measures of uncertainty, to identify areas exceeding health-based guideline values. Methods: The BGS soil metals data for Pb, Cd and As comprise an amalgamation of six different surveys collected over a 34-year period and have up to four samples per km<sup>2</sup>. Ordinary Kriging (OK) and Empirical Bayesian Kriging (EBK) were applied to an 80% stratified sample (i.e. 80% random sample of each survey, comprising 36,802 'training samples'). The remaining 20% 'test sample' (9,202 samples) was used for cross-validation. The predicted standard error generated via the EBK approach was mapped to quantify the uncertainty/error in the interpolated surface. Results: The OK and EBK interpolation methods generated similar soil concentration surfaces, and cross validation with the held-back test data indicated moderate to good model performance: Spearman's rank correlation coefficients 0.83 (Pb), 0.72 (As) and 0.57 (Cd). Overall, the models tended to underestimate metal concentrations, although at lower levels (where the majority of the samples clustered), the models both over and under-estimated metal concentrations. For each metal, the areas of high uncertainty (i.e. high standard errors) were located in the areas with high soil metal concentrations. In terms of small areas exceeding health based guideline values, almost 4% of Lower Layer Super Output Areas (LSOAs) exceeded the UK soil guideline value for As, and 3.6% exceeded the USA EPA hazard standard for Pb for residential children's play areas. No LSOAs exceeded the UK soil guideline value for Cd. Conclusions: These soil metal concentration surfaces can be used to identify areas exceeding health based guidelines.

**P02.3710. Living and Working Conditions of Children and Adolescents Inserted in the Outsourcing Informal and Household Productive Arrangement of Jewelry and Fashion Jewelry in Brazil**

Kelly Polido Kaneshiro Olympio

*Elizeu C. Pereira<sup>1</sup>, Ana Paula Sacone da Silva Ferreira<sup>1</sup>, Ana Paula Sayuri Sato<sup>2</sup>, Frida M. Fischer<sup>1</sup>, Kelly Polido Kaneshiro Olympio<sup>1</sup>*

*1. Environmental Health , School of Public Health, Sao Paulo, Brazil.*

*2. Epidemiology, School of Public Health, Sao Paulo, Sao Paulo, Brazil.*

Abstract: Limeira is a Brazilian city, which has an important role in the production of jewelry and fashion jewelry in Latin America. Among the many problems involved in the productive arrangement of jewelry and fashion jewelry, such as chemical exposure and inadequate work conditions, it is the child labor. The work of this vulnerable population means one of the serious and controversial topics in public health in several countries. The aim of this study was to evaluate the living and working conditions of 11-17-year-old students (n=17), involved in the informal and home productive arrangement of jewelry and fashion jewelry, in Limeira. The participants were divided into 2 groups ("work with jewelry at home" and "non workers"). Two questionnaires were applied during school and vacation times: A comprehensive questionnaire on working and living conditions and a time-budget protocol to fill during 10 consecutive days. This latter includes information to be daily registered on potential main activities performed during wake and rest times around the clock (24h). Chi-squared/Fisher and t-student tests were performed to compare time (minutes) of study, sleep, and leisure between the two groups. No significant differences were detected comparing both student groups regarding age and sex. 15 youths were males (88%) and the age mean was 14.9 years. During the school period, working teens showed the lower mean duration of time to study at home (p=0.030), leisure (p<0.001) and sleep (p<0.001) than non-working students. During the vacation period, working students also showed reduced leisure (p<0.001) and sleep times (p<0.001). In summary, this study shows that working at home has a harmful effect on living conditions of this studied population, affecting both study, leisure and sleeping times. These data should be considered as an exposome component to evaluate long-term health endpoints and their possible causes. This study was funded by FAPESP (2016/11087-8; 2017/14392-9) and CNPq.

## **P02.3720. On the Estimation and Use of Dermal Permeability Coefficients**

John Kissel

*John C. Kissel<sup>1</sup>, Annette L. Bunge<sup>2</sup>*

*2. Chemical Engineering, Colorado School of Mines, Golden, CO, United States.*

Abstract: Two general approaches are most commonly applied to quantitative estimation of dermal absorption of chemicals. The first is fixed fractional or first order absorption. This approach is not generally well grounded in physics, and has obvious limitations, but is simple, convenient and routinely encountered. Dermal absorption can also be more rigorously conceptualized as thermodynamically driven diffusion through a membrane. This permits mathematical representation of the process using Fick's law. In this approach, the key parameter is the permeability coefficient, which is most conventionally estimated as the ratio of flux to driving force, expressed as a concentration gradient, at steady state. The resulting permeability coefficient is vehicle specific. Theoretically such a permeability coefficient should be roughly constant (with allowance for damage, moisture content, interpersonal variation in skin characteristics, etc.) for a given compound, vehicle, temperature and skin location. In practice the standard assumptions required for estimation of permeability coefficients are often violated. Frequently encountered estimation errors include misspecification of the driving force and evaluation of non-steady results using the steady state form of Fick's law. Lack of adherence to theoretically defensible practice has produced unnecessary confusion in the peer-reviewed literature. Current interest in dermal exposure to SVOCs in indoor environments, and to flame retardants in particular, has produced a flurry of recent publications, in multiple journals, in which first order rate constants have been incorrectly described as permeability coefficients. This suggests that lack of familiarity with basic dermal absorption concepts remains an issue within exposure science.

## **P02.3730. The Use and Misuse of Bradford Hill in American Tort Law**

Raymond Neutra

Abstract: More than fifty years ago, Sir Austin Bradford Hill's Presidential Address to the Royal Society of Medicine-The Environment and Disease: Association or Causation?-identified some examinations that could be conducted upon features of epidemiological data that researchers could undertake to assist inferences about the ability of environmental agents to cause disease. We conducted a Westlaw search of largely federal district and appellate court decisions citing "Hill's aspects," "Hill's considerations," or "Hill's criteria" that identified numerous illustrative instances in which Hill's address has been invoked by judges. We will analyze both incorrect and correct uses of the results of the examinations that Hill proposed. Among the legal misinterpretations of Hill that we have found are: (1) Requiring that all of Hill's recommended examinations be carried out (2) Treating the examinations as criteria with yes/no answers as if they were like Koch's Postulates and with symmetric impact of supportive and un-supportive results (3) Requiring statistical significance of associations in each considered study (4) demanding that Rate Ratios be greater than 2.0 (5) Demanding that the body of evidence include epidemiology (6) demanding that the body of evidence include toxicology. All of these demands are contrary to Hill's recommendations. In addition, we argue that understanding the probabilistic foundations of epidemiology shows that Hill is well justified in his recommended examinations of epidemiological evidence and his recommendations for interpreting the results of those examinations to warrant causal inference. We provide numeric examples to show how many of Hill's examinations are like rule-in/ but not rule-out laboratory examinations and that the prior plausibility of an association, ought, indeed to influence our degree of causal certification. Understanding the probabilistic roots of Hill's recommendations provides a deeper justification for them.

**P02.3740. Non-Linear Model Analysis of the Relationship between Cholinesterase Activities in Rats Exposed to 2, 2-Dichlorovinyl Dimethylphosphate and its Metabolite Concentrations in Urine**

Hiroataka Sato

*Hiroataka Sato<sup>1</sup>, Yuki Ito<sup>1</sup>, Chinami Hanai<sup>1</sup>, Masaya Nishimura<sup>1</sup>, Jun Ueyama<sup>2</sup>, Michihiro Kamijima<sup>1</sup>*

*2. Graduate School of Medicine, Nagoya University, Nagoya, Aichi, Japan.*

**Abstract:** Background and aim 2, 2-dichlorovinyl dimethylphosphate (DDVP) is an organophosphate (OP) widely used for the insect pest control operation and to maintain the household environment. However, there are few reports about the relationship between dimethylphosphate (DMP) excreted into urine as a metabolite and health effect. In the present study, the non-linear model analysis was performed to estimate the threshold of DMP corresponding to the cholinesterase inhibition. Methods A total of 40 male Wistar rats (11-week-old) was divided into four groups and orally administered DDVP (control, 0.2, 1.0 and 5.0 mg/kg/day) for two weeks (five-day treatment per week). The blood, brain and urine were collected after the final administration. The cholinesterase (ChE) activities of the brain, red blood cell (RBC) and plasma were analyzed by Ellman method (Voss G et al, 1970). DMP was examined by using gas chromatography-mass spectrometry. Statistical analyses and model estimation were conducted with drc package (version 3.0-1; Ritz C et al, 2015) for R (version 3.4.1). Results Each of the ChE activities in the 5.0 mg/kg/day group was significantly inhibited when compared with the control group (Steel-Dwass method,  $p < 0.05$ ). The relationships between ChE activity and total urinary DMP excretion were represented as dose-response curves by three non-linear models for brain and RBC ChE and one model for plasma ChE. The estimated DMP corresponding to 20% inhibition of ChE was 0.34 mg/24h for brain and 0.11 mg/24h for RBC, which were calculated by averaging the results of three models, and 0.23 mg/24h for plasma. Their lower limits of 95% confidence intervals were 0.04, 0.06 and 0.09 mg/24h, respectively. Discussion and conclusion In this study, the non-linear model analysis, i.e. Benchmark Dose (BMD) analysis (Crump et al, 1984), was used to estimate the reference value of DMP derived from DDVP. The estimated concentration could be used to assess the human health risk of DDVP exposure.

## **P02.3750. Cumulative Risk Assessment Based on Human Biomonitoring Data for Three Anti-Androgenic Phthalates Using the Maximum Cumulative Ratio in Iranian Children**

Maryam Zare Jeddi

*Maryam Zare Jeddi<sup>3</sup>, Yuri Bruinen de Bruin<sup>2</sup>, Ivonne Rietjens<sup>3</sup>, Masud Yunesian<sup>1</sup>*

*2. European comission Joint Research Center, Ispra, Italy.*

*3. Toxicology, Wageningen University and Research, Wageningen, Netherlands.*

**Abstract:** The aims of this study were to estimate the profile, exposure and daily intake of five different phthalates, and to assess the health risks of the cumulative exposure to anti-androgenic phthalates in Iranian children. In the assessment of phthalate exposure, concentrations of three anti-androgenic phthalates including dibutyl phthalate (DBP), butyl benzyl phthalate (BBP), and diethylhexyl phthalate (DEHP) were analyzed in the spot urine sample of 56 Iranian school children aged 6-18 years. In this study, the hazard index (HI) approach is applied to estimate cumulative exposure to three anti-androgenic phthalates. Furthermore, the Maximum Cumulative Ratio (MCR) is used to quantify the degree to which a single chemical drives the cumulative risk of an individual exposed to multiple chemicals. Results: The range of the estimated daily intake was 0.01 µg/kg body weight/day for BBP and 17.85 for DEHP µg/kg body weight/day. However, the result of cumulative risk assessment suggested that the combine exposures to anti-androgenic phthalates were of relatively low concern (HI values in the surveyed participants averaged 0.2). The range of MCR value in the 56 participants was 1.1 to 2.32. The cumulative exposures of concern mainly originated from two of the three anti-androgenic phthalates including DBP and DEHP. Conclusions: Although the hazard index values for all anti-androgenic phthalates were below 1, the detection of all phthalates metabolites in 92.9% of samples population indicates that children are exposed to mixture of phthalates simultaneously. In addition, aside the investigations of phthalates in this regard, take into account that children are exposed to numerous other chemicals with anti-androgenic properties which may also contribute to a cumulative anti-androgenic effect.

## **P02.3770. Emerging Compounds in Standard Reference Material 2585 Organic Contaminants in House Dust**

Jessica Reiner

*Jessica Reiner<sup>1</sup>*

*1. NIST, Charleston, SC, United States.*

Abstract: Standard Reference Materials (SRMs) are homogeneous, well-characterized materials that are used to validate measurements and improve the quality of analytical data ([www.nist.gov/srm](http://www.nist.gov/srm)). Originally issued in 2005, SRM 2585 Organic Contaminants in House Dust was intended for use in evaluating analytical methods for legacy organic pollutants (including polycyclic aromatic hydrocarbons, polychlorinated biphenyls, and chlorinated pesticides) in house dust and similar matrices. This SRM, while intended for analysis of legacy compounds, became an important matrix for the measurement of emerging organic chemicals (polybrominated diphenyl ethers, synthetic musks, per- and polyfluorinated compounds (PFAS), and newer use flame retardants) because interlaboratory studies of these compounds showed considerable disagreements. NIST has been measuring these emerging chemicals in SRM 2585 with the goal of assigning values on the Certificate of Analysis. In late 2017 NIST finished measurements and updated SRM 2585 with the addition of polycyclic musks, PFAS, and selected flame retardants. This presentation will highlight the methods for adding analytes to an existing SRM and provide values for emerging compounds in SRM 2585.

## **P02.3780. Data Quality Evaluation for Epidemiologic Studies Under Amended TSCA**

Francesca Branch

*Francesca M. Branch<sup>1</sup>, Andrea Pfahles-Hutchens<sup>1</sup>, Lauren Brown<sup>2</sup>, Andrea Chiger<sup>2</sup>, Pradeep Rajan<sup>3</sup>, Heidi Hubbard<sup>3</sup>, Julie Melia<sup>4</sup>, Karie Riley<sup>5</sup>*

*5. Versar, Inc., Springfield, VA, United States.*

Abstract: The amended Toxic Substances Control Act (TSCA) requires EPA to conduct chemical risk evaluations to determine whether chemicals present an unreasonable risk to human health and the environment. Any science-based decisions must "use scientific information, technical procedures, measures, methods, protocols, methodologies, or models, employed in a manner consistent with the best available science." To meet these requirements, EPA systematically searched and identified data for 10 existing chemicals that are currently undergoing risk evaluation. Multiple streams of data (engineering, environmental release, exposure, fate, ecological health and human health) were screened for relevancy using eligibility criteria. EPA then developed criteria to assess the methodological quality of the relevant studies, and to determine the extent to which these studies are reliable and unbiased. This presentation will describe the evaluation tool that EPA designed to review epidemiologic data on exposure and health. Epidemiologic studies can contain information both on chemical exposure and human health hazards, and as such will be assessed independently to support the exposure and hazard assessments. EPA used elements of evaluation procedures implemented in past TSCA risk assessments, and adapted/supplemented with elements from other established evaluation tools (e.g., IRIS, OHAT, Money, Lakind) in order to design epidemiologic evaluation criteria that are fit for purpose and fulfill the scientific standards requirements under amended TSCA. The views expressed in this abstract are those of the authors and do not represent Agency policy or endorsement.

## **P02.3790. Spatial Analysis of Environmental Inequalities with Biomonitoring Data: A Cumulative Risk Assessment**

Florent Occelli

*Florent Occelli<sup>1</sup>, Caroline Lanier<sup>1</sup>, Annabelle Deram<sup>1</sup>, Damien Cuny<sup>1</sup>*

*1. EA4483, University of Lille, Lille, France.*

**Abstract:** Differential and not fair exposure to environmental risk factors across socio-demographic groups, called environmental justice (EJ), may contribute to inequalities in health and most often put disadvantaged groups at higher risk for environmental health effects. Main literature has difficulties to consider the potential exposure of populations to different levels of air pollutants. Cumulative and long-term exposures are still seldom considered. We propose a comprehensive EJ methodology to prioritize and characterize neighborhoods which takes into account the cumulative impact of health determinants. For this purpose, the use of environmental biomonitoring is an innovative approach to consider the integrated and long-term exposure to complex air pollution. Cumulative Impact Screening (CIS) methodology was used for two contrasted living areas of France. CIS is based on synthetic and composite index construction. Three scores were attributed to each neighborhood according to a cumulative calculation of key parameters: environmental score (using 3 air biomonitoring parameters: trace elements loads in lichens, lichenic biodiversity and dust deposition on poplar leaves), socioeconomic deprivation score and susceptible population score. Each score can be considered as a dimension of health vulnerability. CIS analysis and maps highlighted the unequal spatial distribution of EJ. After the multi-criteria hierarchization of spatial units, the influence of each dimension was characterized in each neighborhood with radar charts. We demonstrated that environmental biomonitoring is a smart approach to fill the lack of available data on multiple air pollution at the local scale. The tool developed is specific to the territory and transposable, which facilitate adoption by a variety of community and stakeholders and prioritization of public health actions. Correlations between EJ and health data are currently assessed to explain the spatial heterogeneity of chronic disease incidence.

## **P02.3800. Research, Communication, and Policy Change: PFAS in Food Contact Materials**

Tom Bruton

*Tom Bruton<sup>1</sup>, Graham Peaslee<sup>2</sup>, Arlene Blum<sup>1</sup>*

*1. Green Science Policy Institute, Berkeley, CA, United States.*

*2. University of Notre Dame, Notre Dame, IN, United States.*

**Abstract:** Introduction: Poly- and perfluoroalkyl substances (PFAS) are used to provide water- and oil-repellency in consumer products, including food packaging. Some PFAS are persistent and toxic, and can migrate from food contact materials into food. However, there is limited data on PFAS occurrence in food contact materials. This presentation will describe research performed using a novel screening technique to measure the fluorine content of a variety of food contact materials, as a proxy for the presence of PFAS. The presentation will also explain the communications strategy used to publicize the results, as well as policy developments that it helped to prompt. **Methods:** Food packaging and disposable food service ware were collected from U.S. grocery stores, fast food chains, and institutional purchasers. Samples were analyzed for fluorine content using particle-induced gamma-ray emission (PIGE) spectroscopy. A subset of samples was tested for individual PFAS using liquid chromatography/high resolution mass spectrometry (LC/HRMS). Results were publicized using a joint press release strategy and a workshop attended by diverse stakeholders. **Results:** Approximately one third of fast food packaging tested contained fluorine levels indicative of intentionally added PFAS. The LC/HRMS analysis confirmed that the detection of fluorine was associated with the presence of PFAS. These results received widespread media attention. At the same time, purchasers began asking their suppliers of food contact materials about PFAS in their products, prompting some suppliers to reevaluate their manufacturing processes. Legislation restricting the use of PFAS in food contact materials has since been introduced in several states and was recently signed into law in Washington State. **Conclusion:** Targeted research combined with an effective communication strategy can motivate decision makers to reduce the use of potentially harmful chemicals in commercial products.

## **P02.3830. Evaluation of Potential Health Risk of Non-Intentionally Added Substance (NIAS) Food Contact Material**

Deborah Lander

*Deborah Lander<sup>1</sup>, Hien Q. Le<sup>1</sup>, Shawn Gannon<sup>1</sup>, Rajath Mudalamane<sup>1</sup>*

*1. Chemours Company, Wilmington, DE, United States.*

Abstract: Background International Life Sciences Institute (ILSI) recently published a guidance for conducting exposure and risk assessment for non-intentionally added substances (NIAS). With the publication of this guidance, there is increased activity in the food packaging industry to study NIAS and confirmation of safety of food contact materials. The ILSI approach was evaluated using a case study of 2-ethyl-acrolein (EA) as a NIAS in polymeric food contact material (FCM). Methods A risk assessment was performed using the ILSI approach combined with the threshold of toxicological concern approach, a read across to acrolein in which toxicity data based on animal testing and human health risk assessment benchmarks are available. The oral exposure is estimated based on the amount of food in contact with a normalised area of the food contact material, and the release/migration of EA into the food from the material. A risk characterisation ratio (RCR) was estimated based on ingestion route of exposure. Results EA was identified as a possible mutagen based on in-vitro tests but there is very little in-vivo testing. Acrolein also tested positive in in-vitro mutagenicity testing but cancer was not detected in whole animal studies for the oral exposure route. Both substances are unsaturated aldehydes and a read across from EA to acrolein is proposed. The RCRs based on conservative exposure estimates of EA content <42 ppm in the FCM <1 (an indication of no increase in health risk) for both toddlers and adults. Discussion Read-across is one of the most commonly used alternative approaches for data gap filling in global regulatory environments and can reduce the need to generate toxicity data for trace level compounds present in food contact materials as NIAS. The current content levels of EA as NIAS do not indicate an increase in health risk.

**P02.3850. Idiopathic Environmental Intolerance Attributed to Electromagnetic Fields in Magnetic Resonance Imaging Examinees**

Chang-Chih Tsai

*Chang-Chih Tsai<sup>1</sup>, Ya-Yun Cheng<sup>2</sup>, How-Ran Guo<sup>2</sup>*

*1. Department of Emergency Medicine, Chi-Mei Medical Center, Tainan, Taiwan.*

*2. Department of Environmental and Occupational Health, National Cheng Kung University, Tainan, Taiwan.*

**Abstract:** Idiopathic environmental intolerance attributed to electromagnetic fields (IEI-EMF) is defined as a set of symptoms perceived by individuals when they are exposed to electromagnetic fields (EMF). The EMF from magnetic resonance imaging (MRI) scanners are the strongest that the general population may encounter. We conducted a study on the symptoms experienced by MRI examinees to identify associated factors. We recruited participants who were between 20 to 79 years of age at a medical center in Taiwan. The MRI facility was a Philip Achieva 1.5T MRI scanner. All participants were volunteers among examinees who were arranged to receive MRI examinations. We used a standard questionnaire to collect data on demographic characteristics and symptoms before the MRI examination. A questionnaire of the same symptoms was administered again immediately after the MRI examination. We excluded candidates who were arranged to receive a brain MRI or who had history of brain lesions, seizures, psychiatric problems, or claustrophobia. We recruited 200 candidates, and they all completed the questionnaires. We excluded 9 who reported having diplopia, which is not a typical symptom of IEI-EMF and thus was used to identify over-reporting. Of the 191 participants included in the analyses, 37 (19.4%) had symptoms during the MRI examination that were not perceived before the examination ( $p < 0.001$  for the Mc'Nemar test). The five most common symptoms which appeared only after the MRI examination were dizziness, ear discomfort, anxiety, palpitation, and poor attention. Of the 10 participants with self-reported IEI-EMF (5.2%), 9 reported symptoms after the MRI examination, with an odds ratio of 22.92 (95% confidence interval: 2.83-185.7,  $P < 0.001$ ). Further studies are needed to clarify whether the symptoms are caused by the EMF produced by the MRI scanner.

**P02.3860. Concentrations of Pharmaceuticals and Endocrine Disruption Effects in Water Extract Samples in a Concentrated Animal Feeding Operation of Korea**

Kyunghee Ji

*Kyunghee Ji<sup>1</sup>, Bokyoung Kim<sup>1</sup>, Younglim Kho<sup>2</sup>, Kyungho Choi<sup>3</sup>*

*1. Yongin University, Yongin, Korea (the Republic of).*

*2. Eulji University, Seongnam, Korea (the Republic of).*

*3. Seoul National University, Seoul, Korea (the Republic of).*

Abstract: Concentrated animal feeding operations (CAFOs) have been suggested to be one of the significant sources of pharmaceutical residues in the environment. However, limited information is available on the potential risks of major pharmaceutical residues in the aquatic environment near CAFO areas. In the present study, 10 veterinary antibiotics, including sulfonamides, tetracyclines, and cephalosporins, along with three analgesics (acetaminophen, ibuprofen, and mefenamic acid) were measured in water samples collected from the streams that run near a CAFO in Korea. The potential toxic effects of the water extracts on steroidogenesis were evaluated using human adreno-carcinoma (H295R) cell lines. The pharmaceuticals were detected at higher levels in the samples collected downstream of the CAFO than in those collected upstream. Levels of the target pharmaceuticals were lower in the samples collected during the high-flow season than in those collected in the low-flow season. In terms of steroidogenic potential, greater production of 17 $\beta$ -estradiol (E2) was observed in the samples collected near the CAFO than in those collected further away, suggesting that pharmaceuticals from CAFOs may possess endocrine-disrupting toxicity. The increase in E2 production is well supported by significant up-regulation of the aromatase (CYP19A1) gene, which catalyzes the final step in the conversion of androgen to estrogen. Our observations show that the aquatic environment near CAFOs could be heavily contaminated with veterinary pharmaceuticals and analgesics, which could induce endocrine disruption.

## **P02.3880. Quantifying Impacts of Emission Reductions on Air Pollution Equity and Health Effects in New York City**

Amir Hakami

*Robyn Chatwin-Davies<sup>1</sup>, Amir Hakami<sup>1</sup>, Burak Y. Oztaner<sup>1</sup>, Melanie Fillingham<sup>1</sup>, Shunliu Zhao<sup>1</sup>, Amanda Pappin<sup>2</sup>, Iyad Kheirbek<sup>3</sup>, Kazuhiko Ito<sup>3</sup>, Jay Haney<sup>4</sup>, Sharon Douglas<sup>4</sup>, Adjoint Development Team<sup>5</sup>*

- 5. Multiple Universities, Variable, AL, United States.*

**Abstract:** This study examines inequity in exposure to fine particulate matter (PM<sub>2.5</sub>) in New York City and surrounding areas across income groups. By contrasting the sensitivities of public health and equity measures to emissions reductions on a location-by-location basis, this study offers novel yet practical suggestions to coordinate air quality management strategies that prioritize different policy endpoints. Air quality simulations were run using the USEPA's Community Multiscale Air Quality (CMAQ) model and its adjoint version over New York City at 1 km resolution. CMAQ is used to estimate concentration surfaces for quantifying exposure to PM<sub>2.5</sub>. Second, the adjoint of CMAQ was run to estimate the sensitivity of domain-wide inequity parameters to pollution emissions, on a location-by-location basis for different sectors. Preliminary results show that lower income populations in New York City tend to be exposed to higher concentrations of PM<sub>2.5</sub>. We find that emission reductions in Brooklyn, Harlem, and the Bronx would be most beneficial for reducing domain-wide inequity, while reductions in Manhattan would result in increased inequity. We also calculate monetized health benefits per ton of primary PM emissions across the domain, with benefits estimated to be significant (as high as \$10M/ton) and spatially variable across the domain. We propose a novel approach for monetizing air pollution inequity, and find that monetized benefits from inequity reductions are comparable in magnitude (up to \$5M/ton) to health benefits from avoided mortality. We examine hypothetical scenarios where quantified benefits with regards to health an inequity are considered in tandem to coordinate policies that target both endpoints simultaneously. Our results demonstrate that focusing emission reductions on sources that are influential on both environmental justice and public health can yield improvements across multiple policy goals simultaneously.

**P02.3910. Careful - Causal Reasoning for Human Health in Experimental Toxicology and Epidemiology: A Joint Case Study on PFOA**

Rob Jongeneel

*Rob Jongeneel<sup>1</sup>, Rik Bogers<sup>2</sup>, Erik Lebret<sup>2</sup>, Aldert Piersma<sup>2</sup>, Danielle Timmermans<sup>2</sup>, Theo Vermeire<sup>1</sup>*

*1. Centre for the Safety of Substances and Products, National Institute for Public Health and Environmental Protection, Bilthoven, Netherlands.*

*2. National Institute for Public Health and Environmental Protection RIVM, Bilthoven, Netherlands.*

Abstract: The project CAREFUL examines the underlying cultures, issues and reasons behind interactions between toxicologists and epidemiologists. The final aim is to arrive at improvement of the process and content of joint risk assessments and at a better message to stakeholders. Phase 1 of the project will develop a common understanding of the argumentation and the weight-of-evidence elements used in both disciplines and the way inferences about the likelihood of causality are made (Lebret et al., this conference). The joint case study on PFOA will be used to develop and adjust a common framework, also taking into account the toxicological (still rather novel) concepts of Mode of Action (MoA) and Adverse Outcome Pathways of chemicals to etiological understanding of pathophysiology and disease development in humans based on (molecular) epidemiology. The case study of PFOA and other cases will also be used to determine the implications of the new approach for risk communication by practitioners of risk assessment, regulators and other stakeholders. This presentation will show the results of the PFOA case study.

## **P02.3920. The Class Concept: Better Policy and Purchasing for Organohalogenes**

Arlene Blum

*Arlene Blum<sup>1</sup>, Miriam L. Diamond<sup>2</sup>, Tom Bruton<sup>1</sup>*

*1. Green Science Policy Institute, Berkeley, CA, United States.*

*2. Department of Earth Sciences, University of Toronto, Toronto, ON, Canada.*

"Abstract: INTRODUCTION: Most of the 80,000 chemicals in use today have not been adequately tested for toxicity. Chemicals in certain chemical classes, such as families of organohalogenes, have similarities in structure and/or function and also have the potential to cause similar harm. Grouping such substances into classes can lead to a more integrated understanding of their functions, uses, and potential for harm, thus allowing for management actions around entire classes of similar chemicals. It also can prevent the common problem of "regrettable substitution," where a phased out chemical is replaced with a series of closely related "chemical cousins" that lack adequate fate and toxicological data and cause similar harm. METHODS: The class concept was developed during a series of Toxics Reduction Retreats where government, academia, business, and nonprofits came together to develop innovative solutions to reduce the use of chemicals of concern. RESULTS: The "Six Classes" concept identifies six families of substances containing a large proportion of the harmful chemicals commonly found in consumer products. They are: (1) highly fluorinated chemicals, (2) antimicrobials, (3) flame retardants, (4) bisphenols and phthalates, (5) some solvents, and (6) certain metals. CONCLUSIONS: The chemical class concept is a simple framework for reducing the use of harmful substances. It can motivate targeted research and communication around the properties of each class which can contribute to more informed decision making by regulatory agencies, manufacturers and large purchasers. Before using or approving a chemical from one of the "Six Classes," specifiers, purchasers and regulators can ask if the chemical's function is essential. If the function is indeed necessary, they should seek safer chemical or design alternatives. Thus, the class concept can motivate effective action to reduce use of and exposure to harmful chemicals, contributing protecting to human and ecosystem health. "

## **P02.3930. Strategic Communication of Exposure Science and Environmental Epidemiology**

Virginia Guidry

*Virginia Guidry<sup>1</sup>, Elizabeth Marder<sup>3</sup>, Antony Williams<sup>2</sup>*

- 1. Office of Communications and Public Liaison, National Institute of Environmental Health Sciences, Research Triangle Park, NC, United States.*
- 2. National Center for Computational Toxicology, U.S. Environmental Protection Agency, Research Triangle Park, NC, United States.*
- 3. Office of Environmental Health Hazard Assessment, California Environmental Protection Agency, Sacramento, CA, United States.*

**Abstract:** Background: Complex environmental health problems require multidisciplinary solutions and public support. Exposure scientists and environmental epidemiologists can use a range of tools to expand the reach of their work and help translate research findings into informed decisions. We will describe how to manage an online presence, including social media profiles, with a professional lens. Objective: Engaging with traditional media and social media can be daunting, so we will share guidance and concrete examples of how to be effective practitioners. Discussion: Traditional media is still a key source of public information. Effective media interviews require understanding what journalists need, including a timely response and clear, plain language explanations. Describing your science in a non-technical way can be challenging and takes preparation. Social media must be used strategically to maintain high quality and value. We will share examples of message development, for research and related purposes, across social media platforms like Facebook and Twitter. LinkedIn, the premier networking tool, helps to form connections and expose your career to potential employers and collaborators. ResearchGate and Academia provide ways to share manuscripts, presentations, posters, and other communication formats. Such online tools can keep the work alive for much longer than the limited conference presentation time, with a broader audience. We will review environmental health-related examples from active practitioners, common pitfalls, and recommendations for best practices with these platforms. Conclusions: Strategic engagement between scientists and public stakeholders can increase the power and efficiency of science. Engaging in traditional and social media can facilitate the formation and growth of partnerships, increase public awareness of environmental health topics, and inform decisions that can help address environmental health issues on local and global scales.

## **P02.3940. Active Machine Learning in Systematic Literature Reviews: Bias, Fixes, and Appropriate Use**

Cara Henning

*Cara Henning<sup>1</sup>, Michelle Cawley<sup>1</sup>, Heidi Hubbard<sup>1</sup>, Arun Varghese<sup>1</sup>*

*1. ICF, Durham, NC, United States.*

Abstract: Text analytics has emerged as a cost-effective innovation used to support systematic literature reviews in human health risk assessments. Text analytics approaches allow some studies to be removed from consideration without undergoing manual review. Supervised machine learning relies on a training dataset to build models that go on to automatically classify a larger set of unclassified documents. However, manually reviewing references to create the training dataset can be resource intensive. "Active" machine learning is a potential solution that uses an algorithm to focus on the most informative documents, reducing the number of references that must be manually reviewed. We simulate active machine learning by using a set of approximately 7,000 abstracts from the scientific literature that was previously classified by subject matter experts with regard to relevance to epidemiology. We examine the performance of alternative sampling approaches to sequentially expanding the training dataset, specifically looking at uncertainty-based sampling and probability-based sampling. We discover that while such active learning methods can potentially reduce training dataset size compared to random sampling, active machine learning-based predictions of model performance potentially suffer from bias that negates its potential benefits. We discuss approaches and the extent to which the bias resulting from skewed sampling can be compensated. We compare the results from active machine learning to those based on a semi-supervised machine learning method called supervised clustering and show how the latter, with only a small training dataset, can outperform the former in terms of (i) accuracy of model predictions and (ii) the fraction of documents eliminated from review. Finally, we propose a useful role for active learning in contexts where accuracy metrics are not critical and/or where it is necessary to rapidly retrieve a subset of relevant literature.

## **P02.3950. High Dimension Biological Analysis of Carbon Nanotube Toxicity**

Spyros Karakitsios

*2. Far Eastern Federal University, Vladivostok, Russian Federation.*

*3. Medical School, University of Crete, Heraklion, Crete, Greece.*

**Abstract:** The toxic effects of multi-walled carbon nanotubes (MWCNTs) are associated with intracellular oxidative processes related to generation of reactive oxygen species (ROS). This is enhanced by metallic impurities that can be mobilized from the carbon nanotubes to the surrounding biological microenvironment. Aiming at identifying the effects of exposure to purified and unpurified MWCNTs on different biological targets immunological, biochemical, gene expression and biological pathway analyses were carried out on samples from healthy humans and in vitro models. The MWCNTs with higher amount of metallic impurities caused a 1.8-fold increase in lipid hydroperoxide levels, while the number of mature T lymphocytes with reduced potential underwent a more than 3-fold increase, as compared to the purified MWCNTs. Whole genome transcriptomics in lung epithelium cells (A549) and keratinocytes (HaCaT) showed that gene expression is significantly modulated after exposure to purified and unpurified MWCNTs. 48-hour exposure resulted in approximately 500 genes expressed differentially in the case of MWCNTs with different levels of impurities. Similar results were found when we analyzed the data isolating the 25 genes involved in the molecular pathway associated to oxidative stress. The persistence of the induction of genes driving chemokine and cytokine-signaling-mediated inflammation showed the importance of the inflammatory effects of MWCNTs, and in particular the unpurified ones. Pathway analysis showed significant modulation of genes related to the NFkB pathway, after exposure to unpurified MWCNTs, as a result of oxidative stress induction. This may cause a perturbation of the IL-6 pathway that aims to regulate inflammatory processes and compensate apoptotic changes. Overall observed immunological responses related to MWCNT exposure are considered the result of the synergistic effect of systemic (mediated by cells of the exposure routes) and local inflammation (blood cells).

## **P02.3960. Multi-Criteria Assessment of Household Preferences for Reducing Greenhouse Gas Emissions: An Analysis of Household Survey Data from Four European Cities**

Paul Wilkinson

*Paul Wilkinson<sup>1</sup>, Rainer Sauerborn<sup>2</sup>, Helen Fischer<sup>2</sup>, Valerie Louis<sup>2</sup>, Alina Hermann<sup>2</sup>, Dorothee Amelung<sup>2</sup>, Carine Barbier<sup>3</sup>, Ghislain Dubois<sup>4</sup>, Franck Nadaud<sup>3</sup>, Bore Sköld<sup>5</sup>, Carlo Aall<sup>6</sup>*

1. LSHTM, London, United Kingdom.
2. University of Heidelberg, Heidelberg, Germany.
3. CIRED, Nogent-sur-Marne, France.
4. TEC-Conseil, Marseille, France.
5. University of Umea, Umea, Sweden.
6. Western Norway Research Institute, Sogndal, Norway.

**Abstract:** Objective To assess household preferences for reducing greenhouse gas (GHG) emissions with respect to criteria of CO<sub>2</sub>e emissions, health impact and cost. Setting Mid-size cities in France, Germany, Norway and Sweden (the HOPE project). Method An inventory of 65 GHG reduction actions was assessed using a CO<sub>2</sub>e emissions, health impact and cost calculator for 309 households. The impact of each action on health was graded using a five-point scale (slightly negative, no impact, and three grades of health benefit). Each action was then compared in terms of these three dimensions (CO<sub>2</sub>e reduction, cost, health) using scores which gave alternative priority weightings to each dimension. The results were examined in relation to the proportion of respondents declaring their willingness to implement each action. Results Actions rated most highly on the combined CO<sub>2</sub>e reduction-health-cost score included switching towards an increasingly vegetarian diet, reducing motor vehicle use in favour of public transport and/or walking and cycling, giving up ready meals, and measures to improve insulation of the home (roof, walls, windows). However, most households were unwilling to make substantial shifts towards becoming vegetarian or towards reducing motor vehicle use. Actions that respondents were often willing to implement and scored highly on the three dimensions of impact included: eating 30% more vegetarian food, walking and cycling instead of using public transport, 'eco-driving', and improvements of roof and window insulation. Conclusion Most householders appear willing to make appreciable changes to their lifestyle and home in order to help achieve GHG emissions reductions, including (but not limited to) moderate (not extreme) dietary modification, some reduction in private vehicle journeys, and home energy efficiency improvements. Though such actions may alone not be sufficient to meet pressing GHG reduction targets.

## **P02.3970. Stakeholder Engagement for Decision-Making on Urban Air Pollution Control**

Nelzair Vianna

*Nelzair Vianna<sup>1</sup>, Andre Fraga<sup>2</sup>*

*1. Oswaldo Cruz Foundation, Salvador, Brazil.*

*2. Secretary of Sustainable City and Innovation of Salvador, Salvador, Bahia, Brazil.*

**Abstract:** Air pollution has been a major problem in cities around the world and a challenge for public health in the 21st century. The local scientific evidence is crucial to decision-making and urban planning. Risk analysis methodology is based on an intersectoral and interdisciplinary approach that promotes stakeholder engagement. Few studies have focused on a discussion of newly developed tools that facilitate dialog between scientists, civil society, and urban planners. **Objective:** To discuss tools capable of engaging stakeholders and providing scientific evidence to support policies on urban air pollution control and urban planning in Salvador, Bahia-Brazil. **Methodology:** Researchers presented scientific evidence to local government officials regarding the results of a local study evaluating the replacement of the city bus fleet and its influence on air quality. Considering the initiatives proposed by the Paris agreement, Salvador joined an international alliance of cities that agreed to fight climate change. The dialogue between scientists and decision-makers has promoted efforts to combat climate change in partnership with C40 (Compact of Mayors) to provide scientific evidence on health, environmental, economic and social impacts. Data collection involved local stakeholders. **Results:** Our risk analysis approach promoted dialogue among the local stakeholders, highlighting the relevance of implementing policies, the need to improve public transport and the energy matrix. The improvement in indicators demonstrates that local actions are crucial in fighting climate change. Civil society involvement was stimulated by risk communication through local media and presentations in the community. Risk management includes planning improvements in public transportation and promoting new urban green spaces. **Conclusion:** We showed that involving stakeholders in different phases of scientific research facilitates the dialogue necessary for decision-making.

## **P02.4000. Evaluation of the Applicability and Reliability of Environmental Exposure Models for Nanomaterials to Regulatory Risk Assessment**

Natasha Chander

*Natasha A. Chander<sup>1</sup>*

*1. Environment and Climate Change Canada, Ottawa, ON, Canada.*

Abstract: Environment and Climate Change Canada is required to perform science-based risk assessments under the Canadian Environmental Protection Act (CEPA). The risk assessment process takes into consideration both the hazardous properties and environmental exposure of a substance. Canada has gathered significant experience in the risk assessment of chemical substances through the Chemicals Management Plan (CMP). However, the risk assessment of nanomaterials poses some challenges, including uncertainty regarding nanomaterial lifecycle and environmental fate. Consequently, the use of environmental exposure models would be of particular interest to characterize the fate and behaviour of nanomaterials in the environment, and to estimate Predicted Environmental Concentrations (PECs). This poster presents a review of the available environmental exposure models and tools specific to nanomaterials. It will discuss the relevance of these models in the Canadian regulatory context, and will consider their reliability with respect to predicting the fate and presence of nanomaterials in the environment.

## **P02.4010. Case Studies of Human Integrated Risk Assessment for Phthalates and PFCs in Korea**

Jong-Hyeon Lee

*Jong-Hyeon Lee<sup>1</sup>*

*1. Research Institute of Environmental Health and Safety, EH R&C Co., Seoul, Korea (the Republic of).*

Abstract: Recently, in Korea, human integrated risk assessment and management (HIRAM) program of chemicals in consumer product and food has launched by Korean FDA. The HIRAM program tried to integrate two different data sources for risk assessment; the external and internal exposure assessment both in personal level and population level. First of all, both external media monitoring and biomonitoring data in personal level were conducted to analyze the knowledge and data gap for HIRAM and to suggest refined assessment strategy. The refined aggregate exposure assessment has been applied to the general population and find out who and how many is population at risk. Finally, the refined aggregate risk assessment was compared with biomonitoring data for general population independently conducted by Korean EPA, and FDA. Case studies for DEHP and PFCs were conducted to compare aggregate exposure with internal exposure estimated from biomonitoring data using toxicokinetic models. In the case of DEHP with fast kinetics, aggregate exposure assessment in personal level confirmed 45% of internal exposure. DBP showed only 15% of the coverage of external exposure to the internal exposure. Person exposure assessment for phthalates did not cover direct exposure scenarios from consumer products. In the case of PFOA/PFOS, 75% and 25% of internal exposure was explained by external exposure. PFOS (half-life: 6.3 years) showed lower coverage than PFOA (half-life: 2.3 years). Most of exposure PFOA/PFOS were from food ingestion. The lower ratio of external and internal exposure would come from the relative high contribution of past exposure due to slow kinetics. Personal monitoring needs to be conducted to cover indirect and direct exposure scenarios of consumer product. Age-structured toxicokinetic models are needed to refine the reverse dosimetry for chemical with slow kinetics.

**P02.4020. Vulnerable Populations and Personal Care Products: The Role of Estimating Exposure to Products Used Primarily by Infants and Young Children**

Sandra Kuchta

*Sandra Kuchta<sup>1</sup>, Leona MacKinnon<sup>1</sup>, Melissa Shaw<sup>1</sup>, Virginie Bergeron<sup>1</sup>, Angelika Zidek<sup>1</sup>*

*1. Health Canada, Ottawa, ON, Canada.*

Abstract: Infants and young children are often key sub-populations of interest when assessing exposure to chemicals for human health risk assessments. As developing humans, children have distinct behavioral characteristics and potential routes of exposure that contribute to the unique differences in their susceptibility to environmental exposures. These include, but are not limited to, increased time on the floor, dust ingestion and mouthing of objects. In addition, there are many products that are marketed for use specifically by infants and children, for example diaper cream and baby wipes. No regulatory guidance specific to cosmetics and personal care products with a focus on infants and young children is currently available. This poster will discuss the unique considerations that go into estimating exposures to products used primarily on/by infants and young children. An overview of exposure factors compiled over the last 15 years, as well as the challenges and uncertainties associated with these approaches to risk assessment will be discussed. A few case studies will also be presented highlighting the use of these considerations to quantify chemical exposure in this subpopulation for regulatory risk assessment. These case studies will include substance groupings under the Government of Canada's Chemicals Management Plan such as phthalates, as well as other select substances.

## **P02.4030. Canadian Specific Exposure Factors for Certain Personal Care Products**

Leona MacKinnon

*Leona MacKinnon<sup>1</sup>, Virginie Bergeron<sup>1</sup>, Sandra Kuchta<sup>1</sup>, Angelika Zidek<sup>1</sup>*

*1. Health Canada, Ottawa, ON, Canada.*

Abstract: Humans use a variety of personal care products (PCPs) every day. Estimating human exposures to chemicals found in PCPs requires information on the frequency of use and amount of product used. This type of information is usually obtained from various questionnaires and surveys and is available from regulatory guidance documents and in the scientific literature; however, very little data exists for the Canadian population. The Canadian Health Measures Survey (CHMS), a national survey that collects important health information from individuals aged 3 to 79 years old, included some questions regarding the use of certain grooming products by Canadians in Cycle 1 (2007-2009) and Cycle 2 (2009-2011), which sheds some light on Canadian use patterns. This poster will highlight Canadian specific data on the frequency of use of certain PCPs by adults, teens and children as young as 3 years old. The poster will also illustrate how this data is being used by the Existing Substances Risk Assessment Bureau (ESRAB) for risk assessments conducted under Canada's Chemicals Management Plan. Results will be presented on how the use of certain PCPs by Canadians compares with use pattern data from the US and Europe.

## **P02.4040. Health and Security in a Global Digital Transforming Society: Risks and Opportunities**

Yuri Bruinen de Bruin

*Yuri Bruinen de Bruin<sup>1</sup>, Josephine McCourt<sup>1</sup>, Stylianos Kefalopoulos<sup>1</sup>*

*1. Knowledge Management Service Joint Research Centre , European Commission, Ispra, Italy.*

Abstract: Thanks to knowledge produced during Human Genomics and Exposome projects, we now know approximately 70% of all human diseases can be explained by 'exposure-throughout-life'. Exposure Science and its combination of ICT and Omics will support the further understanding of the patterns of diseases and will open up even more possibilities, like personalised medicine, not just for treatment but also probabilistic prevention as a function of environmental parameters. Combining these three areas will offer risk managers to take measures that protect the general population, specific groups and individuals and will eventually offer means to repair alternated DNA in the future reorienting the healthcare systems away from costly 'one-size-fits-all' approach. New technologies such as internal and external biomonitoring sensors produce huge amount of data causing an ever further digitalization of health data boosting preventive and curative health care options. Sensors in combination with the release of specific dosages for medical treatments accessible via the internet require high demands on secure data collection, storage, handling and ownership. Like many of the big technological developments outcomes can be used for the good but also for the bad supporting the development of secure health-related information preventing unwanted CBRNE-type (Chemical, Biological, Radiological, Nuclear, and Explosives) incidents. In many countries new streams of health data are generated. These data are important building blocks for a new approach to health research and delivery, tailored to the protective needs the population. Therefore, linking security with health in the digital transformation of the current society is of utmost importance. This presentation will address the opportunities and threats in the frame of security and health in a global digital transforming society and aims to interact with exposure practitioners to develop best practices in field of secure health information.

## **P02.4050. Nitrogen Dioxide: From Science to Policy**

Ninon Lyrette

*Ninon Lyrette<sup>1</sup>, Barry Jessiman<sup>1</sup>, Ron Newhook<sup>1</sup>*

*1. Health Canada, Government of Canada, Ottawa, ON, Canada.*

Abstract: The Canadian Ambient Air Quality Standards (CAAQS) are a key element of the Air Quality Management System, a collaborative approach implemented by federal, provincial and territorial governments for improving air quality in Canada. This presentation will outline the considerations from the science and the process leading to the development of the CAAQS for nitrogen dioxide (NO<sub>2</sub>). Health Canada's 2016 human health risk assessment for NO<sub>2</sub> is a comprehensive review of the most relevant science. This assessment provides clear evidence of health risks of NO<sub>2</sub> to Canadians and forms the primary scientific foundation for the development of the CAAQS. While NO<sub>2</sub> contributes to the formation of ozone and fine particulate matter, the CAAQS are based on clear evidence linking NO<sub>2</sub> exposure to health effects on the respiratory system. There is also evidence related to effects on the cardiovascular system, on fetal growth and birth weight, and premature death. Epidemiological studies indicate that there is an almost linear relation between short- and long-term exposure to ambient NO<sub>2</sub> concentrations and adverse effects on human health, with no apparent threshold. Given this, any incremental reduction in ambient NO<sub>2</sub> concentrations will directly lead to reduced risks for serious health effects on Canadians for which a large segment of the population is susceptible. Based on these findings, it was concluded that both short-term and long-term standards were needed to protect against these health effects. The health evidence, in combination with other factors such as the environmental effects and the current and projected NO<sub>2</sub> levels, were taken into consideration in the CAAQS development through the Canadian Council of Ministers of the Environment (CCME) mediated multi-stakeholder process. The NO<sub>2</sub> CAAQS, which are specifically targeted at reducing population exposure, were endorsed by the CCME in November 2017, and issued in the Canada Gazette in December 2017.

## **P02.4060. A General Framework to Deal with Uncertainty in Expert Panel Risk Assessment**

Sandrine Fraize-Frontier

*Sandrine M. Fraize-Frontier<sup>1</sup>, Isabelle Albert<sup>2</sup>, Soraya Boudia<sup>3</sup>, Nathalie Bonvallot<sup>4</sup>, Amélie Crépet<sup>1</sup>, Philippe Glorennec<sup>4</sup>, David Makowski<sup>2</sup>, Claude Saegerman<sup>5</sup>, Moez Sanaa<sup>1</sup>, Jessica Tressou<sup>2</sup>, Celine Brochot<sup>6</sup>*

1. *Risk Assessment Department, Anses, Maisons-Alfort Cedex, France.*
2. *MIA, INRA, Paris, France.*
3. *Paris Descartes University, Paris, France.*
4. *EHESP, Rennes, France.*
5. *Liège University, Liège, Belgium.*
6. *INERIS, Verneuil en Halatte, France.*

**Abstract:** The importance of clarifying and disclosing uncertainties in risk assessment (RA) has been acknowledged for several decades. However, even today, these uncertainties do not receive the attention they deserve to well inform decision makers. To overcome this situation, diverse regulators, health and safety agencies, and other bodies involving in RA at national, European or international level have recently mobilized themselves by reasserting the need to integrate uncertainty analysis in the RA process and making practical recommendations. The French agency for food, environmental and occupational health and safety (Anses) is one of them. This work presents the general framework developed by the Anses Expert Working Group on Methodology in Risk Assessment. Two critical points were addressed: A typology of uncertainties and a homogenized approach to deal with uncertainty analysis in different areas (human health related to the environment, work and food, animal health and welfare, and plant health). The proposed typology is divided into four classes (Context, Corpus of knowledge, Assessment methodology and Communication), according to the logic of an expert appraisal process. A five-step iterative approach, systematically preceded by a stage for planning the assessment, was proposed as a generic approach of uncertainty analysis. Especially, the importance of considering the decision-making context of the assessment from the planning stage is stressed. The iterative approach was developed to be flexible enough to enable the assessors ensure the analysis is proportionate to and fit for purpose of the assessment. As part of a testing stage, the general framework was applied to different case studies dealing with diverse areas (health RA in humans, animals and plants). This testing phase was carried out in collaboration with different expert panels. It concluded that the generic and flexible nature of the proposed framework should be able to harmonize the practices in RA.

## **P02.4070. Reviews in Environmental Health: How Systematic are they?**

Juleen Lam

*Patrice Sutton<sup>1</sup>, Natalyn Daniels<sup>1</sup>, Juleen Lam<sup>1</sup>, Hannah Archibald<sup>1</sup>, Kristin Davis<sup>1</sup>, Hazel Tesoro<sup>1</sup>, Tracey Woodruff<sup>f</sup>*

*1. OB/GYN & Reproductive Sciences, University of California, San Francisco, San Francisco, CA, United States.*

**Abstract:** Background: Systematic review methodologies are gaining traction in the environmental health field, with aims to inform research and evidence-based decision-making. How the methods and results of a systematic review compare to those of a traditional expert-based narrative review on the same topic has not been empirically evaluated. Methods: We identified reviews through the literature searches conducted during 3 Navigation Guide systematic review case studies: (1) Air Pollution and Autism Spectrum Disorder; (2) PBDEs and IQ/ADHD; and Formaldehyde and Asthma. We compared each review to the 9 domains of the Literature Review Appraisal Toolkit (LRAT), a structured appraisal of the methodological strengths and weaknesses of a review. We evaluated each review to determine if it was a self-identified systematic review, and compared the review conclusions to determine if they were broadly consistent with the conclusion of the Navigation Guide case study. Results: We identified a total of 30 reviews eligible for the LRAT appraisal. All non-systematic reviews fell short of all LRAT domains except for "directness of evidence." Among self-described systematic reviews implementation of all of the features of robust systematic review methods was highly variable. Roughly half of all the reviews arrived at conclusions that were broadly consistent with the Navigation Guide systematic review method case study conclusions on the same topic. Conclusions: Systematic reviews are not all equal in quality and result in more transparent and reproducible results than the non-systematic reviews on the same topic. The lack of consistently applying robust methods to synthesize the available data identified in this small study may be prevalent in the field as these methods are new to environmental health. Environmental health scientists should be trained in improved methods for evidence integration and work closely with information specialists in conducting reviews.

## P02. Occupational Issues 2

### **P02.4080. Network on the Coordination and Harmonisation of European Occupational Cohorts (OMEGA-NET)**

Michelle Turner

- 9. Division of Environmental Epidemiology, Institute for Risk Assessment Sciences, Utrecht University, Utrecht, Netherlands.*

Abstract: OMEGA-NET is a 4-year COST Action, starting in October 2017, funded by EU. Paid employment is an essential component of adult life and a major determinant of health and healthy ageing. However, in recent years there has been limited coordination and promotion of European health research on occupation and employment as causes of health problems and inequalities. Europe currently has some of the most valuable occupational, industrial, and population cohorts worldwide. The lack of integration of these cohorts hampers the optimal exploitation of these resources, essential to underpin evidence-based interventions and policy. The overarching concept of OMEGA-NET is to create a network to optimize the use of occupational, industrial, and population cohorts. OMEGA-NET will advance i) collaboration of existing cohorts, with extensive contemporary information on employment and occupational exposures, ii) coordination and harmonisation of occupational exposure assessment efforts, and iii) facilitation of an integrated research strategy for occupational health in Europe. We will inventory numerous cohorts with occupational information in Europe; implement an online interactive tool with detailed information on existing cohorts; facilitate work on harmonisation of occupational exposure and health outcome information and new protocols for data collection; connect scientific communities on occupational health in Europe and beyond. Collaboration through OMEGA-NET will enhance the scientific output from individual studies and facilitate pooled studies, data sharing, and transfer of tools and skills to make greater and more efficient use of existing cohorts. The work will provide a foundation for an enhanced evidence base for the identification of health risks and gains related to occupation and employment to foster preventive strategies and policies. Researchers from countries outside Europe can participate in COST Actions on the basis of ascertained mutual benefit.

## **P02.4090. Multicomponent Monitoring for Safety Management of Greasepaints**

Wanseo Kim

Wanseo Kim<sup>1</sup>, Hyojong Park<sup>1</sup>, Hyeri Kwon<sup>2</sup>, Jinsun Heo<sup>2</sup>, Jaeho Shin<sup>2</sup>, Younglim Kho<sup>1</sup>

*1. Department of Health, environment & safety, Eulji University, Gyeonggi-do, Korea (the Republic of).*

*2. Department of Senior Healthcare, BK21 Plus Program, Graduate School, Eulji University, Gyeonggi-do, Korea (the Republic of).*

**Abstract:** Background/Aim Greasepaints are usually used by actors to make up. In recent years, such as films, musicals and Halloween. Demand for Greasepaint is increasing as people enjoy cultural activities such as movies, performances and Halloween. However, due to the use of Greasepaints, people are exposed to harmful substances such as heavy metals and preservatives and so on. In Korea, greasepaints are managed by Ministry of Food and Drug Safety. In this study, we investigated the current status of the management of 6 preservatives, 6 parabens, 5 heavy metals, formaldehyde, 1,4-dioxane, methanol, and phthalate for the safe use of greasepaints. We purchased 95 greasepaints (water 55, oil 40) in Korea and monitored them. We check the actual condition of ingredient marking and check whether the use regulation is well maintained. Methods We pretreated greasepaints in the manner prescribed in Guidelines for Method of Ingredient Analysis for Banned Ingredients in Cosmetics designed by Ministry of Food and Drug Safety. We analyzed using HPLC-DAD(6 preservatives, formaldehyde), UPLC-MS/MS(6 parabens), GC-FID(methanol), GC-MS(3 phthalates), HS-GC-MS(1,4-dioxane), ICP-MS(4 heavy metals), Mercury analyzer. Results Detection rate was as follows; mercury 7.4%, lead 51.6%, antimony 62.1%, cadmium 28.4%, arsenic 31.6%, benzyl alcohol 1.1%, phenoxy ethanol 49.5%, sorbic acid 5.3%, benzoic acid 17.9%, dehydroacetic acid 5.3%, salicylic acid 4.2%, methyl paraben 15.8%, ethyl paraben 4.2%, propyl paraben 8.4%, butyl paraben 13.7%, isopropyl paraben 1.1%, formaldehyde 4.2%, 1,4-dioxane 17.9%, methanol 98.9% and phthalates 1.1-2.1% respectively. Conclusions In this study, blending limit of greasepaints sold in Korea is well maintained. This study is meaningful that it provides quantitative information on greasepaints and provides baseline data for the safety management of greasepaints by providing actual information on ingredient marking.

**P02.4120. Breast Cancer Risk by Occupation in Females and Males in Ontario, Canada: Results from the Occupational Disease Surveillance System (ODSS), 1983-2016**

Jeavana Sritharan

*Jeavana Sritharan<sup>1</sup>, Jill S. MacLeod<sup>1</sup>, Chris McLeod<sup>3</sup>, Alice Peter<sup>2</sup>, Paul A. Demers<sup>1</sup>*

*1. Occupational Cancer Research Centre, Cancer Care Ontario, Toronto, ON, Canada.*

*2. Population Health and Prevention, Cancer Care Ontario, Toronto, ON, Canada.*

*3. School of Population and Public Health, University of British Columbia, Vancouver, BC, Canada.*

**Abstract:** Background: While breast cancer is one of the most commonly diagnosed cancers among women, it accounts for fewer than 1% of cancer cases in men worldwide. Few prior studies have been able to study breast cancer in working men. This study uses data from the recently established Occupational Disease Surveillance System (ODSS) to examine risk of breast cancer in both women and men across different occupation groups. Methods: The ODSS was established through the linkage of existing administrative data and contains information on 2,190,246 Ontario workers (1983-2016). Workers were followed up for breast cancer diagnosis in the Ontario Cancer Registry (OCR). Cox-proportional hazard models were used to calculate age-adjusted hazard ratios (HR) and 95% confidence intervals (CI). Results: A total of 17,865 and 492 breast cancer cases were identified in working women and men, respectively. Across both sexes, statistically significant ( $p < 0.05$ ) elevated risks were observed in management (w: HR 1.57, 95% CI 1.42-1.73; m: HR 2.41, 95% CI 1.24-4.66), administrative and clerical (w: HR 1.16, 95% CI 1.11-1.21; m: HR 1.56, 95% CI 1.13-2.13), and teaching occupations (w: HR 1.49, 95% CI 1.41-1.59; m: HR 2.82, 95% CI 1.40-5.66). Other statistically significant elevated risks were observed in social sciences, nursing and other health, transport and equipment operating, and sales commodity occupations for both sexes. Conclusions: Similar findings were found in women and men that warrant further investigation into job-related factors, such as sedentary behaviour, stress, shift work, and for some occupations, radiation exposure. The findings from this study, if validated in other study samples, may help focus breast cancer prevention and education efforts for both females and males.

## **P02.4140. Occupational Noise Exposure is Associated with Hypertension in China: Results from Project ELEFANT**

**Abstract: Background/Aims:** Noise pollution is the second-leading environmental cause of health issues, including increased blood pressure (BP) and cardiovascular disease. Our study sought to examine the association between occupational noise exposure with risk of hypertension and BP by hypertension stage in young Chinese adults. **Methods:** We utilized data from 124,286 young adults (aged 18-40) within Project ELEFANT, a multi-cohort study based in Tianjin, China. Questionnaire data was used to identify high levels of occupational noise exposure, and BP measured by automated device (mmHg). Hypertension stage was diagnosed according to the 2017 High Blood Pressure Clinical Practice Guidelines. We applied adjusted logistic regression models to identify associations with hypertension risk, and examined interactions with BMI, gender and residence in separate models. **Results:** Occupational noise exposure was associated with an increase of 0.23 mmHg in BP (95% CI: 0.10-0.38,  $p=0.0009$ ) among participants with elevated BP, 0.15 mmHg (0.06-0.22,  $p=0.0008$ ) in those with Stage 1 hypertension and 0.41 mmHg (0.27-0.55) with Stage 2 hypertension. The noise exposure-BMI interaction was positively associated with an increase of 0.71 mmHg (0.44-0.99,  $p<0.0001$ ) in elevated blood pressure, 0.78 mmHg (0.60-0.96,  $p<0.0001$ ) in Stage 1 hypertension and 2.06 mmHg (1.73-2.38,  $p<0.0001$ ) in Stage 2 hypertension. Further, noise exposure was associated with a higher risk for Stage 1 (odds ratio: 1.67, 1.47-1.86) and Stage 2 hypertension (1.35, 1.35-2.05) in males than females. Finally, noise exposure-urban interaction was associated with an increase of 0.32 mmHg (0.17-0.48,  $p<0.0001$ ) in elevated blood pressure and 0.44 mmHg (0.27-0.59) in Stage 2 hypertension. **Conclusions:** Occupational noise exposure is associated with increased blood pressure in young adults with elevated blood pressure and Stage 1 & Stage 2 hypertension. Furthermore, noise exposure displays interaction with BMI, gender and residence.

**P02.4150. The Role of School Environments and Occupational Stressors for Michigan Public School Teachers: An Assessment of Stress and Health**

Geila Rajae

*Mozhgon Rajae<sup>1</sup>, Geila Rajae<sup>2</sup>, Samantha Karson<sup>1</sup>, Ashley McCullough<sup>1</sup>*

*1. Public and Environmental Wellness, Oakland University, Rochester, MI, United States.*

*2. University of Michigan, Ann Arbor, MI, USA*

**Abstract:** School teachers experience tremendous occupational stress, which can lead to low retention, missed work days, and lower quality of life. Teachers working in low-resource school districts face unique challenges and stressors, with some experiencing poor indoor air quality, crowding, and biological exposures. The objective of this pilot research was to assess cumulative stressors in low and high-resource public school districts, and the influence these stressors have on perceived stress and biological stress response for teachers. Teachers were recruited from four low- and high-resource school districts in southeast Michigan. Participants were surveyed on demographics, occupation, health, and perceived stressors. Blood pressure and heart rate were measured at the time of the survey. Individual salivary cortisol samples were collected in the afternoon (n=3) and evening (n=3) following the survey. An environmental survey of each teacher's classroom and school was conducted to assess room and school conditions, noise, and proximity to major roadways and industry. Fifty-nine (n=59) teachers were recruited from 26 public schools. Teachers at low-resource school districts had higher afternoon cortisol levels (4.12 nmol/L) and a higher prevalence of hypertension (54%), although not significant, compared to high-resource school district teachers (3.11 nmol/L and 45%, respectively). Low-resource school district teachers had significantly higher reported occupational stress ( $p=0.004$ ); specifically concerning environmental quality, relationships, and demands; and were more likely to feel stressed "very often" and "fairly often" (82%) compared to high-resource school district teachers (45%). Teachers' classrooms and schools were less likely to be classified as well-maintained in low-resource school districts. This research will support priority-setting for reducing occupational and environmental stressors for school districts to improve teacher health outcomes and retention.

**P02.4170. The Influence of Vitamin D Receptor, Metallothionein 1A and 2A Gene Polymorphisms on the Lead Toxicity to the Sensory Nervous System in the Chronic Lead- Exposed Workers**

Hung-Yi Chuang

*Hung-Yi Chuang<sup>1</sup>*

*1. Department of Public Health, Kaohsiung Medical University, Kaohsiung City, Taiwan.*

**Abstract:** Background and objective: Lead had neurotoxicity in peripheral sensory systems. Variant vitamin D receptor (VDR) genes and polymorphisms of Metallothioneins (MTs) were associated to lead toxicity. But rare relationship between lead neurotoxicity and polymorphisms were discussed before. This study investigated the relationship among the polymorphisms of the VDR, MT1A, MT2A and lead toxicity to sensory nervous system in chronic lead-exposed workers. Methods: We measured 181 workers' vibration perception thresholds (VPT) and current perception thresholds (CPT) as neurological outcomes. The outcome variables were then correlated to the subject's index of long-term lead exposure that was calculated by the subject's serial blood lead data in a period of working duration. The polymorphisms of VDR (Bsm rs1544410, Apa rs7975232, and Taq rs731236), MT1A (rs11640851 and rs8052394) and MT2A (rs10636 and rs28366003) were defined. The potential confounders, including age, gender, body height, smoking, alcohol consumption and working history, were also collected and analyzed in multiple regressions. Results: MT2A rs28366003(AG/AA) and MT1A rs8052394 (GG/AA) had significant different in all frequency of hand and foot CPT/hand and foot CPT 2000Hz, and had the negative regression coefficients. MT1A rs11640851 (AA/CC) had significant difference in all neurological outcomes except hand and foot VPT. In MT2A rs10636, more C allele showed more influence in all three frequency of hand CPT comparing CC with GC and GG. Among VDR, Apa rs7975232 (CC/AA) had most difference in all three frequency of hand CPT, and Taq rs731236(TC/TT) had difference in hand VPT. Conclusion: Individuals with AG genotype for MT2A rs28366003 and GG genotype for MT1A rs8052394 had neural protective effects. On the other hand, CC genotype for Apa (rs7975232) of VDR, CC genotype for MT2A rs10636 and AA genotype for MT1A rs11640851 had susceptibilities to neurotoxicity.

## **P02.4190. Exposure to Metal Fume Particulate Matter and Receptor for Advanced Glycation End Products in Shipyard Welders**

Min-Chien Lo

*Min-Chien Lo<sup>1</sup>, Chia-Chi Chou<sup>1</sup>, Hsiao-Chi Chuang<sup>4</sup>, Chih-Hong Pan<sup>3</sup>, Gu-Jyun Lin<sup>1</sup>, Saou-Hsing Liou<sup>2</sup>, Ching-Huang Lai<sup>1</sup>*

Abstract: Inhalation of metal-rich PM<sub>2.5</sub> produces reactive oxygen species (ROS) in the body, which may cause Maillard reactions, produce advanced glycation end products (AGEs). The interaction between the receptor of AGEs (RAGE) and its ligand AGEs triggers the inflammatory signal transduction, elevating risk of chronic diseases including diabetes mellitus. This study was assess the association between exposure to metal fume fine particle matter and production of AGE and RAGE. This study conducted in cross-sectional design and consisted of 52 welding workers and 29 office workers. The exposure assessment was performed for all individuals with a personal sampler to measure eight working hours exposure to metal-rich PM<sub>2.5</sub> on Monday. On Tuesday morning, participants were instructed to fast for at least 10 hours prior to urine and blood sampling. Urinary metals were measured by ICP-MS. AGE and RAGE product was analyzed by ELISA and Flow Cytometry respectively. Multivariable linear regression model was used to assess association between urinary metals concentration and AGE and RAGE expression. PM<sub>2.5</sub> exposure concentrations were 379.93±4.71 µg/m<sup>3</sup> and 154.47±3.56 µg/m<sup>3</sup> in welders and administrative personnel, respectively. RAGE expressions were 1500.78±1743.56 a. u. and 741.05± 537.03 a. u. in welders and administrative personnel, respectively. However, AGE did not significantly differ between these two groups. There was no significant correlation between PM<sub>2.5</sub> and AGE or RAGE. After adjusted for confounders, urinary chromium concentration ( $\beta=0.242$ , 95%CI 0.024-0.339, P=0.025) and urinary cadmium concentration ( $\beta=0.333$ , 95%CI 0.017-0.165, P=0.017) were significantly associated with RAGE expression. However, no significant effect of urinary metals concentration on AGE was found. Exposure to metal fume particulate matter in welders were significantly associated with increasing RAGE expression. Inflammatory response of increased RAGE expression of welders should be further investigated.

## **P02.4200. Quantification of Trisaminohexyl Isocyanurate (TAHI) as a Biomarker of HDI Isocyanurate Exposure in the Plasma and Urine of Automotive Spray Painters**

Leena Nylander-French

*Zachary Robbins<sup>1</sup>, Wanda Bodnar<sup>1</sup>, Zhenfa Zhang<sup>1</sup>, Avram Gold<sup>1</sup>, Leena A. Nylander-French<sup>1</sup>*

*1. Department of Environmental Sciences and Engineering, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States.*

Abstract: Biological monitoring of occupational exposure to 1,6-hexamethylene diisocyanate (HDI)-containing spray-paints is limited to analysis of metabolites of HDI monomer although polymeric HDI isocyanurate constitutes the predominant inhalation and skin exposures for workers in the automotive paint industry. In order to investigate HDI isocyanurate and HDI monomer exposure-biomarker associations, we developed a novel method to quantify trisaminohexyl isocyanurate (TAHI) as a biomarker of HDI isocyanurate exposure in biological samples collected from occupationally exposed spray-painters. Plasma and urine samples were acid hydrolyzed, extracted with dichloromethane, and derivatized with acetic anhydride prior to analysis of the derivatized product, trisacetamidohexyl isocyanurate (TAAHI), with nanoflow ultra-performance liquid chromatography coupled to nano-electrospray ionization tandem mass spectrometry (nano-UPLC-ESI-MS/MS). Analytical and internal standards required for analysis were not available commercially and, subsequently, were synthesized in-house. The calibration curves and method detection limits (MDL) were sensitive and specific for spiked control plasma (N = 11; 0.03 - 3.99 µg/L; r = 1.000; MDL = 0.02 µg/L) and spiked control urine (N = 13; 0.06 - 7.98 µg/L; r = 0.998; MDL = 0.03 µg/L). TAHI was detected in 23 of 112 plasma samples (13 of 46 workers) with an arithmetic mean ± standard deviation of 0.014 ± 0.042 µg/L, and in 130 of 417 urines samples (36 of 48 workers) with an arithmetic mean ± standard deviation of 0.204 ± 0.705 µg/L. The quantification of TAHI as a biomarker of HDI isocyanurate exposure is essential for future research on the pharmacokinetics of uptake and elimination in order to determine the relative potency and dose-relationships between HDI monomer and oligomer exposure.

## **P02.4210. Exposure to Metal Fume Particulate Matter and NO in Exhaled Breath in Shipyard Welders**

Kuan-Yu Shen

*kuan-yu Shen<sup>1</sup>, Hsiao-Chi Chuang<sup>2</sup>, Chih-Hong Pan<sup>3</sup>, Saou-Hsing Liou<sup>4</sup>, Ching-Huang Lai<sup>5</sup>*

Abstract: Exposure to metal fume particulate matter has been linked to numerous adverse health endpoints. Clinical researches have been clarifying the relation of Fractional nitric oxide (FeNO) with airway inflammation in asthma. Despite this, limited data examining the relation of metal fume particulate matter exposure and NO in exhaled breath in welders. We conducted a cross-sectional study. Study participants consisted of 52 welders and 29 office workers. Exposure assessment was based on eight-hour measurement with a personal PM2.5 sampler of exposure to metal fume fine particle matter on Monday. On Tuesday morning, participants were instructed to fast for at least 10 hours prior to urine sampling. The concentration of NO in exhaled breath, an indicator of acute bronchial inflammation and oxidative stress, was measured first, using the portable analyzer. Then a portable spirometer was used to perform the forced expiratory measurements. PM2.5 exposure concentrations were  $379.9 \pm 4.7 \mu\text{g}/\text{m}^3$  and  $154.5 \pm 3.6 \mu\text{g}/\text{m}^3$  in welders and office workers, respectively. Welders had lower levels of NO in exhaled breath than that of office workers after adjusting for confounds, though the difference was not significant. Participants with current smoking habit had significant lower NO levels compared to non-smokers. Individual urinary metal such as Mn, Co, Ni, and Fe was associated with NO in exhaled breath in all workers after adjusting for confounds. However, only individual urinary Ni, or Fe metal was associated with NO in exhaled breath in welders. No association between any lung function indicators and NO level in exhaled breath was found. We concluded that some particular metals from metal fume particulate matter exposure may be associated with decreasing NO level in exhaled breath in welders.

**P02.4220. Chemical Exposure Related to Occupational Environment of Woven Fabric Workers, Northern of Thailand**

Kamphon Saeng-lam

*Kamphon Saeng-lam<sup>1</sup>, Saowanee Norkaew<sup>2</sup>, Katiya Ivanovitch<sup>2</sup>*

*1. Faculty of Fine and Applied Arts, Thammasat University, Lampang, Lampang, Thailand.*

*2. Faculty of Public Health, Thammasat University, Bangkok, Bangkok, Thailand.*

Abstract: Woven fabric is the famous products in Northern part of Thailand. According to the process of woven product, workers used several chemical along processing which can be contaminate in community environment. This study was conducted using a qualitative study with the aim to determine chemical exposure related to occupational environment of woven fabric workers in Northern part of Thailand. An in-depth interview was completed by face to face from workers in woven fabric with natural dye community during 2017. There were all of members in natural dye community getting involved in this study. The results shown that participant age between 50-70 years. Most of the participants were female. The process of woven fabric product included 1) cotton fibres cleaning, 2) weave cotton fabric and 3) fabric dye. Workers reported that they use detergent in cotton fibres cleaning. For fabric process, workers reported that zinc mordant and natural ash mordant have used in this process, also used chemical and natural materials. All of participants never treat their waste water from the fabric processing before pour. These are activating factors associated with environment problems, especially chemical contaminant in working environment and community environment. The finding suggested that the risk factors of chemical exposure related to occupational environment among woven fabric workers should be investigate. Furthermore, the improvement of working environment and educational related to working activities should be conducted in this community.

## **P02.4250. Reduction in County Population Rates of Sinonasal Cancer Following Improvements in Industrial Hygiene at a Nickel Refinery**

Tom K Grimsrud

*Tom K Grimsrud<sup>1</sup>, Steinar R Berge<sup>2</sup>*

*1. Department of Research, Cancer Registry of Norway, Oslo, Norway.*

*2. Occupational Health Service unit, Glencore Nikkelverk AS, Kristiansand, Norway.*

**Abstract:** Background The Cancer Registry of Norway has virtually complete national data on incident cancers through more than 60 years. In 1973, the Registry published the first study of respiratory cancer among workers at a nickel refinery in Kristiansand, in the county of Vest-Agder. Very high risks had already been found in nickel workers elsewhere (Wales, UK; Ontario, Canada). The Kristiansand refiners had an overall sinonasal cancer rate 28 times the expected, and lung cancer 4.8 times in excess of national background rates. Sinonasal cancer is a rare disease with population rates less than 10<sup>-5</sup> in men (world standard), but the rate in surrounding Vest-Agder county was more than doubled (1953-1971). Later improvements in the refinery process and industrial hygiene have been described. We have found suggestions of a downward trend in respiratory cancer among the refiners. Methods For this ecological study, we used population data for Vest-Agder and national age-specific rates in men to derive locally expected numbers of sinonasal cancer for six decades (1955-2014). The refinery's health care unit contributed the numbers of sinonasal cancer in workers with local residence. Results Before 1995, sinonasal cancers among present or former employees fully accounted for the excess at the county population level. For the last two decades, county numbers were in line with those expected from the national rates (0.8 and 0.7 of expected). Conclusion Lower nickel concentrations and respiratory protection appear to have eliminated the excess of sinonasal cancer, although low background rates may have left a remaining low to moderate risk undetected. Population mobility may also dilute local rates. Potential conflicts of interest: No funding was received for the study. TKG is employed by the Cancer Registry, a governmental institution. SRB is employed by the nickel refinery's health care unit, required by Norwegian law to act as a free and independent advisor in work environment questions.

## **P02.4260. Carcinogenicity of Styrene**

Nadia Vilahur

*Kathryn Z. Guyton<sup>1</sup>, Neela Guha<sup>1</sup>, Nadia Vilahur<sup>1</sup>, Yann Grosse<sup>1</sup>, Fatiha El Ghissassi<sup>1</sup>, Veronique Bouvard<sup>1</sup>, Lamia Benbrahim-Tallaa<sup>1</sup>, Amy L. Hall<sup>1</sup>, Heidi Mattock<sup>1</sup>, Kurt Straif<sup>1</sup>*

*1. Evidence Synthesis and Classification, Monographs Program, International Agency for Research in Cancer, Lyon, Sweden.*

Abstract: Styrene is a high production volume chemical primarily used to produce polystyrene polymers and it is found in workplace air in the reinforced plastics industry. Styrene is also present in tobacco smoke, and in air pollution. In March 2018, a Working Group of leading scientists from 24 countries met at the International Agency for Research on Cancer (IARC) in Lyon, France, to re-evaluate the carcinogenicity of styrene (in addition to styrene-7,8-oxide and quinolone, not addressed here), based on published human, animal and mechanistic data. The most informative epidemiological studies were occupational cohort studies conducted in different countries in the reinforced plastics industry, suggesting that exposure to styrene causes lymphohaematopoietic malignancies, with higher consistency in the evidence for leukaemias and in particular myeloid leukaemia. However, confounding by other co-occurring occupational exposures such as butadiene, or the presence of biases or chance due to, for example, small sample sizes could not be ruled out. Evidence in humans for other cancer sites, including lung cancer, was sparse or inconsistent. Inhalation studies in rodents showed increased risk for different types of tumours in both sexes. A large body of mechanistic evidence showed that styrene is rapidly absorbed, distributed and metabolized in humans, potentially leading to genotoxic effects in exposed humans and it can modulate receptor-mediated effects and cell proliferation in various human cell lines and animal models. The conclusion of this evaluation of styrene regarding its carcinogenicity in humans is currently under embargo due to publication in the Lancet Oncology, but results will be presented in full at the time of the ISEE meeting.

## **P02.4270. Depression and Related Risk Factors among High Tech Workers in Southern Taiwan**

Chien-Yuan Huang

*Chien-Yuan Huang<sup>1</sup>, How-Ran Guo<sup>2</sup>*

*1. Department of Occupational medicine, Chimei medical center, Tainan, Taiwan.*

*2. Department of Environmental and Occupational Health, College of Medicine, National Cheng Kung University, Tainan, Taiwan.*

**Abstract:** Introduction: Depression, which might lead to the acculmulation of stress and in turn lead to various physical and mental illnesses, has become an important issue among workers in the high-tech industry. In recent years, there were many reports on the work stress associated with depression, but few were from Taiwan. Therefore, we conducted a study to evaluate the associations between depression and burnout among high tech workers. Methods: We recruited workers working in a scientific park in southern Taiwan between Janurary 1 and December 31, 2016. Information on demographic characteristics was collected through a self-administrated questionnaire. Participants also completed Taiwanese Depression Scale (TDS), Chinese Job Content Questionnaire (C-JCQ), and reported habits of smoking and drinking. Results: There were 865 workers participated in this study. We observed positive associations between depression and supervisor, perceived stress, economic stress, work stress and social support (all with  $p < 0.05$ ). After adjusting for other factors, we found perceived stress (adjusted odds ratio [AOR] =3.42, 95% confidence interval [CI]: 2.03-5.76), supervisor (AOR=5.30, 95% CI=1.25-22.43), passive work stress (AOR=3.21, 95% CI=1.69-6.09), and high work stress (AOR=4.83, 95% CI=2.11-11.07), were independent risk factors of depression. Conclusion: Among the high tech workers, depression is associated with perceived stress, management and work stress. Therefore, intervention strategies for depression should take into consideration these factors.

**P03.0010. The Association between Thermal Comfort and Sleep Patterns: Preliminary Results from the Center for Research on Environmental and Social Stressors in Housing across the Life Course (CRESSH) Sleep Sub-Study**

Dayna Johnson

*Dayna A. Johnson<sup>1</sup>, Na Guo<sup>2</sup>, Emily Kaplan<sup>2</sup>, Sara Gillooly<sup>3</sup>, Francine Laden<sup>3</sup>, Gary Adamkiewicz<sup>3</sup>*

- 1. Sleep Medicine, Harvard Medical School, Boston, MA, United States.*
- 2. Sleep and Circadian Disorders, Brigham and Women's Hospital, Boston, MA, United States.*
- 3. Environmental Health, Harvard T.H. Chan School of Public Health, Boston, MA, United States.*

Abstract: Thermally comfortable sleep environments are necessary for optimal sleep. Vulnerable populations (e.g. racial/ethnic minorities, lower socioeconomic status) are disproportionately affected by adverse housing conditions, which likely impact thermal comfort and sleep. We investigated the influence of thermal comfort on objective and subjective sleep patterns among a racially/ethnically diverse population. Between 2016-2017, participants (N=44) of the CRESSH Sleep Sub-Study underwent 7-day actigraphy for objective measures of sleep duration and sleep efficiency. During a home visit, participants self-reported thermal comfort as "too cold" or "too hot" to fall or stay asleep as well as subjective sleep duration and quality. We conducted chi-square tests to determine whether thermal comfort was related to a short sleep duration (<7 hours), poor sleep efficiency (<90%), or subjective restless sleep. Participants were predominately female (63.6%), minority (38.6% Hispanic, 11.4% Black, 15.9% Asian), college-educated (56.8%), and married (40.9%). The average age was 53.6 years (standard deviation: 16.3). Approximately 47.7% of the sample had a short sleep duration and a poor sleep efficiency and 52.3% reported restless sleep. Most of the sample (56.8%) reported being "too hot to fall or stay asleep" at least once per week; whereas 45.4% reported being "too cold to fall or stay asleep". Participants who reported "too hot" compared to those who did not, were more likely to have restless sleep (56% vs. 26%, P=0.05) and a poor sleep efficiency (68% vs. 42%, P=0.09). "Too hot" was not associated with sleep duration and "too cold" was not associated with the explored sleep measures. Among our racially/ethnically diverse population, poor sleep was common and uncomfortable temperatures were reported barriers to initiating or maintaining sleep. Being "too hot" was related to poor sleep quality, thus thermal comfort may be a point of intervention to improve sleep in this population.

### **P03.0020. Future Wildfires and Air Pollution-Related Health Damages**

Henry Roman

*Henry Roman<sup>1</sup>, Meredith Amend<sup>1</sup>, Maria val Martin<sup>3</sup>, Susan C. Anenberg<sup>2</sup>*

*1. Industrial Economics, Inc. (IEc), Cambridge, MA, United States.*

*2. George Washington University, Washington, DC, United States.*

*3. University of Sheffield, Sheffield, United Kingdom.*

**Abstract:** Climate change is expected to increase wildfire frequency and intensity around the globe. Examples of these impacts can already be observed in the recent historical record, and as the effects of climate change continue to intensify over the coming century, several studies predict a continuation of this trend. A recent modeling study demonstrated that global area burned may increase by approximately 8% by 2050 and 30% by 2100. This increase has the potential to nullify anticipated declines in anthropogenic sources of fine particulate matter (PM<sub>2.5</sub>), as wildfires become more dominant sources of PM<sub>2.5</sub> around the globe. We use these model simulations of wildfire area burned from the present day to 2100 to generate the first quantitative estimates of the magnitude and economic value of air pollution-related health impacts worldwide associated with future fire activity. We analyze projected PM<sub>2.5</sub> for two alternative scenarios considering both climatic and socio-economic drivers of fire activity, where climatic changes are characterized by representative concentration pathways (RCPs) and socio-economic drivers by shared socio-economic pathways (SSPs). We apply the U.S. Environmental Protection Agency's Environmental Benefits Mapping and Analysis Program - Community Edition (BenMAP-CE) and the 2015 Integrated Exposure Response (IER) Function from the Global Burden of Disease study to quantify the global health impacts associated with fire-related emissions for the present day and future under the two scenarios at a resolution of 0.1 degree x 0.1 degree worldwide. Results presented include the health burden from wildfire PM<sub>2.5</sub> globally, by world region, and by country, for the present day, 2050 and 2090 under two scenarios of climate change and socioeconomic development.

**P03.0030. The Climate and Health Impacts of Achieving National Target Levels of Liquefied Petroleum Gas (LPG) Adoption in Cameroon: Findings from Policy Modelling According to the Cameroon National LPG Masterplan**

Daniel Pope

*Chris Kypridemos<sup>1</sup>, Elisa Puzzolo<sup>2</sup>, Borgar Aamaas<sup>3</sup>, Kristin Aunan<sup>3</sup>, Daniel Pope<sup>1</sup>*

*1. Public Health & Policy, University of Liverpool, Liverpool, United Kingdom.*

*2. The Global LPG Partnership, London, United Kingdom.*

*3. CICERO Center for International Climate Research, Oslo, Norway.*

**Abstract:** Introduction As part of its commitments to becoming an emerging economy by 2035, the Cameroon Government has set a target that by 2030, 58% of the population will be using Liquefied Petroleum Gas (LPG) as a cooking fuel, compared to less than 20% in 2014. The aims of this study were to estimate the potential impacts of this planned LPG expansion (Masterplan) on population health and climate change mitigation. Methods We developed mathematical models to measure the health and climate impacts of expanding LPG adoption for household cooking in Cameroon over two periods: 1. Short-term (2017-2030); Comparing Master Plan with a counterfactual LPG adoption of 32% in 2030, in line with current trends. 2. Long-term (2031-2100, climate modelling only); Assuming Cameroon will become a mature and saturated LPG market by 2100 (73% adoption, based on Latin American countries). We compared this with a counterfactual adoption of 41% by 2100, in line with current trends. Results By 2030, successful implementation of the masterplan was estimated to save about 23,000 lives and avert 760,000 disability-adjusted-life-years compared to naturally increasing trends in LPG adoption. For the same period reductions in component emissions of more than a third were found, leading to an annual cooling effect of -4.4 Mt CO<sub>2</sub>-equivalent (calculated with 50% renewable biomass), by applying the Global Warming Potential with a 100-year time horizon, and a global cooling of -0.1 milli °C in 2030. For 2100, a cooling impact for the Masterplan leading to LPG saturation (73%) was estimated to be -0.70 milli °C assuming 90% renewable biomass, increasing to -0.93 milli °C with 50% renewable biomass. Conclusion Meeting the government target of 58% of the population using LPG through successful implementation of the Masterplan will have significant positive impacts on population health and on climate, through reductions of emissions influencing climate and associated global cooling.

### **P03.0040. Regional Variations in Future Temperature-Attributable Mortality**

Jae Young Lee

*Jae Young Lee<sup>1</sup>, Ho Kim<sup>1</sup>*

*1. Graduate School of Public Health, Seoul National University, Seoul, Korea (the Republic of).*

Abstract: Regional projection studies for future temperature-attributable mortality due to climate change have been actively conducted for decades. Recently, these projection studies tried to estimate the future mortality more accurately by considering not only climate change but also population change and adaptation. However, these regional projection studies are heterogeneous in various aspects of their study designs. On the other hand, there are a few studies which examined the climate-change-induced health effects on global scale. However, these global-scale studies only compared the regional effects of climate change without detailed analysis as to why they vary. As a result, we still have poor understanding on the sources of the regional variations in climate-change-induced mortality. Qualitatively speaking, the regional mortality variations are the results of regional temperature increase and vulnerability. The temperature increases are known to vary from region to region depending on the various factors. The temperature vulnerability varies depending on factors such as population composition and medical level. It is important to deeply understand the key factors and their impacts on future temperature-attributable mortality. This study estimated the future temperature-related mortality in many locations worldwide. The temperature-mortality relationships were estimated using DLNM, and the effect of climate changes on future temperature-related mortality were predicted under RCP scenarios. Then, we examined the contributions of various factors on the regional variations in the mortality. In this analysis, we introduced a new normalized metric which shows the effect of climate change with respect to 100 ppm increase in global CO<sub>2</sub> concentrations. This study is important to relate the future mortality and 100 ppm increase in CO<sub>2</sub> concentration, thereby providing guidance for setting a carbon budget. Also, this study shows key factors in regional mortality variations.

### **P03.0050. Awareness, Risk Perception, and Protective Behaviors for Extreme Heat and Climate Change in New York City**

Jaime Madrigano

*Jaime Madrigano<sup>1</sup>, Kathryn Lane<sup>2</sup>, Nada Petrovic<sup>3</sup>, Munerah Ahmed<sup>2</sup>, Micheline Blum<sup>4</sup>, Thomas Matte<sup>5</sup>*

- 1. RAND Corporation, Arlington, VA, United States.*
- 2. New York City Department of Health and Mental Hygiene, New York City, NY, United States.*
- 3. Columbia University, New York, NY, United States.*
- 4. Baruch College Survey Research, New York, NY, United States.*
- 5. Vital Strategies, New York, NY, United States.*

Abstract: Preventing heat-related illness and death requires understanding who is at risk and why, and options for intervention. We sought to understand the drivers of socioeconomic disparities in heat-related vulnerability in New York City (NYC), the perceived risk of heat exposure and climate change, and barriers to protective behaviors. A random digit dial telephone survey of 801 NYC adults aged 18 and older was conducted from September 22-October 1, 2015. Thirteen percent of the population did not possess an air conditioner (AC), and another 15% used AC never/infrequently. Odds of not possessing AC were greater for non-Hispanic blacks compared with other races/ethnicities, OR=2.0 (95% CI: 1.1, 3.5), and for those with low annual household income, OR=3.1 (95% CI: 1.8, 5.5). Only 12% reported going to a public place with AC if they could not keep cool at home. While low-income individuals were less likely to be aware of heat warnings, they were more likely to be concerned that heat could make them ill and that climate change would affect their health than participants with a higher household income, OR=1.6 (95% CI: 1.0, 2.3). In NYC, lack of access to AC partially explains disparities in heat-related health outcomes. Our results point to opportunities for knowledge building and engagement on heat-health awareness and climate change adaptation that can be applied in NYC and other metropolitan areas to improve and target public health prevention efforts.

## **P03.0060. Increasing Access to Cooling in the Community: A Trial Heat Relief Network for Toronto**

Kelly Sabaliauskas

*Kelly Sabaliauskas<sup>1</sup>, Kyle Silveira<sup>1</sup>, Donna Ansara<sup>1</sup>, Symron Bansal<sup>1</sup>, Nicole Pynduira<sup>1</sup>, Stephanie Gower<sup>1</sup>, Kate Bassil<sup>1</sup>, Rajesh Benny<sup>1</sup>, Howard Shapiro<sup>1</sup>, Gayle Burse<sup>1</sup>*

*1. Toronto Public Health, Toronto, ON, Canada.*

Abstract: Toronto Public Health (TPH) estimates that extreme heat contributes to an average of 120 excess deaths per year in Toronto. Very hot weather or extended periods of heat can increase health impacts among all people. Toronto Public Health coordinates the Hot Weather Response Plan under which key partners undertake activities aimed at reducing heat-related illness, including opening seven cooling centres when either a Heat Warning or Extended Heat Warning is in effect. Cooling Centres are designated air-conditioned locations that provide a place for people and their pets to escape the heat, rest, drink water, have a light snack and get information on how to prevent heat-related health impacts. To inform how Toronto can best offer cooling to vulnerable residents, in 2017, TPH conducted a jurisdictional scan of heat relief programs across North America and identified common features of heat relief facilities, including the following factors that make them more effective: 1) maximizing the number, and broadening the definition of facilities that are designated as heat relief facilities; 2) selecting facilities where people already choose to spend their time; and 3) allocating resources to promote and coordinate work. Based on the results of this scan, TPH will be promoting a Heat Relief Network that incorporates nearly 200 air conditioned libraries and community centres for the 2018 heat season. In addition, the Heat Relief Network will attempt to overcome barriers that prevent residents from using the existing Cooling Centre program including: limited access to transportation, fear or inability to leave home, stigma and reluctance to spend time in a place without activities. This presentation will focus on the population needs, program design, resident engagement and challenges encountered while implementing the Heat Relief Network.

## **P03.0070. Leveraging Community Partnerships to Advance Disaster Research Response: A Qualitative Analysis**

Erin Haynes

- 2. Department of Environmental and Occupational Health Sciences, University of Washington, Seattle, WA, United States.*
- 3. Community and Behavioral Health, University of Iowa, Iowa City, IA, United States.*

**Abstract:** In response to concerns about increasing disasters, the NIH created the Disaster Research Response Program (DR2) as "the national framework for research on the medical and public health aspects of disasters and public health emergencies." We sought to identify perceived facilitators and barriers to community engagement (CE) in DR2 and examine how existing community partnerships can be leveraged to facilitate timely and effective DR2. We conducted key informant interviews with 15 National Institute of Environmental Health Science Environmental Health Science Centers Community Engagement Core (CEC) Directors. Interviews elicited information about current community partnerships and familiarity and experience with DR2. We also explored the possibility of developing a CE response team that could be rapidly deployed to disaster-affected communities to facilitate translational research and CE activities. Interview notes were inductively coded and qualitatively analyzed. Common barriers to CE in DR2 included lack of DR2 experience, complexity of coordinating multiple external research groups, issues related to rapid IRB approval or IRB coordination across institutions, perceived detrimental impacts to well-developed community relationships, and varying expectations and priorities among community groups and researchers. The importance of established working relationships with communities before a disaster occurs was a recurrent theme and emphasizes the important role that CECs and practice-based connections play in DR2. A DR2 CE response team was identified as an opportunity worthy of further exploration. The results of this study will help inform the NIH DR2 program and provide information on how to best quickly and effectively engage community partners when conducting DR2.

**P03.0080. The Relationship of Climate Variability and Particulate Matter on Birth Weight in Seoul, Republic of Korea**

Jong-Hun Kim

*Jong-Hun Kim<sup>1</sup>, Hae-Kwan Cheong<sup>1</sup>*

*1. Social and Preventive Medicine, Sungkyunkwan University, Suwon, Korea (the Republic of).*

**Abstract:** Background: Birth weight is an indicator of in utero environment including exposure to environmental factors. Climate variability is associated with both meteorological factors and changes in atmospheric pollutant concentrations. The authors aimed at assessing the effect of climate variability and air pollutant on birth weight in an Eastern Asian metropolitan city. Methods: We have linked the individual birth data, Ocean Nino index, the particulate matter less than 10 µg in diameter (PM10) concentration, and the meteorological factors from 2000 to 2016 in Seoul, Republic of Korea. Using a generalized additive model, we analyzed the exposure-response relationship between average Ocean Nino Index, average temperature, and average PM10 during pregnancy and change of birth weight. Results: Birth weight significantly increased to 4.08 (95% CI. 2.80, 5.37) g per 1 degree Celsius increment of average Ocean Nino Index. Birth weight sharply decreased to -4.85 (95% CI. -6.84, -2.86) g per 10 µg/m<sup>3</sup> increment of average PM10 concentration. As the average temperature increased, the birth weight tended to decrease by -1.1 (95% CI. -4.65, 2.45) g per 1 degree Celsius increment, but it was not statistically significant. Conclusions: We have confirmed that the effects of climate variability, temperature and PM10 during pregnancy interact with each other. The rise in temperature due to climate change and air pollution can be important environmental risks affecting birth weight in the 21st century.

**Abstract: Background/Objective:** High ambient temperature is shown to influence birth outcomes, however, few studies have assessed heat's effect during the fetal development period on congenital heart defects (CHDs), especially in transitional seasons. We examined and compared the associations between extreme heat and CHD phenotypes in summer and spring, assessed their geographical differences, and compared different heat indicators. **Methods:** We identified all 5,848 CHD cases and 5,742 controls (without major structural defects) from the National Birth Defects Prevention Study, a United States (U.S.) multicenter population-based case-control study. Extreme heat events (EHEs) were defined by using 95th (EHE95) or 90th (EHE90) percentile of daily maximum temperature and its frequency and duration during postconceptional weeks 3-8. We used a two-stage Bayesian hierarchical model to examine both regional and study-wide associations. Exposure odds ratios (ORs) were calculated using multivariate logistic regression analyses, while controlling for potential confounding factors. **Results:** Overall, we observed no consistent relationships between maternal EHE exposure and CHDs in most regions. However, we found that 3-11 days of EHE90 in both summer and spring was significantly associated with ventricular septal defects (VSDs) study-wide (ORs ranged: 2.17-3.24). EHE95 in spring were significantly associated with conotruncal defects and VSDs in the South (ORs: 1.23-1.78). Most EHE indicators in spring were significantly associated with increased septal defects (VSDs and atrial septal defects (ASDs)) in the Northeast. **Conclusion:** While generally null results were found, longer heat durations were associated with increased risks for VSDs and ASDs, mainly in the South and Northeastern U.S., as well as transitional months in spring when using multiple heat indicators. Further research is needed to confirm our findings.

**P03.0110. Public Health Professionals' Perceptions of Dengue Control in the Face of Climate Change: A National Survey among China CDC Staff**

Peng Bi

*Michael Xiaoliang Tong<sup>1</sup>, Peng Bi<sup>1</sup>*

*1. School of Public Health, University of Adelaide, Adelaide, SA, Australia.*

**Abstract:** Background: As an important climate-sensitive disease, dengue fever has been a serious public health problem in China, which is particularly important in the context of climate change. Health professionals play a significant role in the control and prevention dengue. The aim of this study was to explore public health professionals' perceptions of dengue control and prevention in the context of climate change in China. Methods: A cross-sectional survey was conducted among public health professionals of 15 Centres of Disease Control and Prevention (CDC) in China to gauge their perceptions of dengue control and prevention in the context of climate change. Descriptive analysis and logistical regression were performed. Results: In total, 1,051 questionnaires were distributed, and 973 questionnaires were completed. More than 75% of participants indicated climate change would affect vector-borne diseases, and more than 70% believed climate change would affect dengue fever, especially those from Southwest, Central and East China. Nearly 70% of participants from Yunnan Province and half from Prefectural/County CDCs indicated dengue re-emerged and occurred in new geographic areas. Furthermore, 41.4% of participants indicated current prevention methods and control programs were effective in reducing dengue incidence, and 35.4% thought the public was well informed about how to reduce the risk of dengue. Additionally, participants thought mosquitoes in high-density, imported cases, climate change and internal migrant population were main risk factors for dengue in China. Conclusion: This study found the majority of public health professionals endorsed that climate change would affect vector-borne diseases and dengue fever in China. Participants had perceived dengue emergence/re-emergence and expansion in geographic areas in certain regions. Most participants urgently advocated better dengue prevention methods and control programs, and health education for the public is needed.

### **P03.0120. Projected Temperature-Related Years of Life Lost from Stroke Caused by Climate Change**

Guoxing Li

*Guoxing Li<sup>1</sup>, Qun Guo<sup>1</sup>, Xiaochuan Pan<sup>1</sup>*

*1. environmental and occupational health, peking university, Beijing, China.*

**Abstract:** Global warming has attracted worldwide attention. Numerous studies have indicated that stroke is associated with temperature; however, few studies are available on the projections of the burden of stroke attributable to future climate change. We aimed to investigate the future trends of stroke years of life lost (YLL) associated with global warming. We collected death records to examine YLL in Tianjin, China, from 2006 to 2011. We fitted a standard time-series Poisson regression model after controlling for trends, day of the week, relative humidity, and air pollution. We estimated temperature-YLL associations with a distributed lag nonlinear model. These models were then applied to the local climate projections to estimate temperature-related YLL in the 2050s and 2070s. We projected temperature-related YLL from stroke in Tianjin under 19 global-scale climate models and 3 different greenhouse gas emission scenarios. The results showed a slight decrease in YLL with percent decreases of 0.85%, 0.97%, and 1.02% in the 2050s and 0.94%, 1.02%, and 0.91% in the 2070s for the 3 scenarios, respectively. The increases in heat-related annual YLL and the decreases in cold-related YLL under the high emission scenario were the strongest. The monthly analysis showed that the most significant increase occurred in the summer months. Future changes in climate are likely to lead to an increase in heat-related YLL, and this increase will not be offset by adaptation under both medium emission and high emission scenarios. Health protections from hot weather will become increasingly necessary, and measures to reduce cold effects will also remain important.

### **P03.0130. Implementation of Real-Time Surveillance Data to Improve the Swedish Heatwave Early Warning System**

*2. Public Health Agency, Stockholm, Sweden.*

**Abstract:** Background As heatwaves are becoming more common with climate change and with trends of increasing vulnerability to heat in Sweden, the role of the Swedish heatwave early warning system is becoming more important. Currently the warning system is managed by the Swedish Met Office and warnings are issued based on temperature alone. To further develop the warning system, we have investigated the possibility to use other types of real-time data to get better estimate of the health impacts from heatwaves. Methods Data on daily maximum temperatures and mortality was collected and combined with data on the number of calls to the nurse advise lines and over-hospitalization. We also investigated the effects of winter mortality on the temperature-mortality relationship during summer. Data was collected for Stockholm and Scania county. Results Findings show that the number of calls to the nurse advise lines for certain symptoms can act as an effect modifier for the heat-mortality relationship in the county of Scania, both the same day as well as in the coming days. A high winter mortality was associated with a lower risk during periods with high temperatures. Over-hospitalizations during heatwaves were associated with an elevated mortality risk, especially for cardiovascular mortality. Over-hospitalizations will also affect mortality in the near future case of a heatwave. Discussion the results suggest that the impacts of heat on mortality is altered by health data that might be available in real-time. This could be used to inform the early warning system and help the transition into a consequence based rather than a weather based system. This work is currently under way for other types of weather warnings and this type of input will increase community's possibility to make informed decisions on preventive actions prior to a heatwave.

### **P03.0140. Spatial and Temporal Characteristics of *Vibrio Parahaemolyticus* in the Chesapeake Bay**

Benjamin Davis

*Benjamin J. Davis<sup>1</sup>, John Jacobs<sup>2</sup>, Andy DePaola<sup>3</sup>, Frank Curriero<sup>1</sup>*

*1. Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States.*

*2. National Centers for Coastal Ocean Science, National Oceanic and Atmospheric Association, Oxford, MD, United States.*

*3. Angelo DePaola Consulting, Coden, AL, United States.*

Abstract: *Vibrio parahaemolyticus* naturally occurs in estuaries and is a leading cause of seafood-borne illness. It is therefore necessary to develop ecological prediction tools for shellfish harvesting waters. Such predictions need adequate spatial and temporal resolution as bacterium abundance fluctuates frequently. Previous work identified environmental determinants of *V. parahaemolyticus* in the tidal waters of the Chesapeake Bay using a large data set (n= 1,385) collected from 148 monitoring stations between 2007-2010. Regression models were developed using water samples analyzed by qPCR along with spatially- and temporally-indexed water quality data. Previously identified relationships with temperature and turbidity were confirmed, while more complex relationships were identified for nitrogen and phosphorus. Non-linear associations with salinity were determined to be a function of both low temperature and turbidity. Recent work attempted to develop *V. parahaemolyticus* prediction models using time-indexed and 1- and 2-month lagged water quality measures. Tobit regression models were evaluated using cross-validation methods to quantify prediction bias and uncertainty. The results were promising, indicating that water quality data can provide adequate prediction for bacterium presence and abundance, and that lagged measures provide complimentary or superior predictive power when compared to time-indexed measures. Current work is expanding variable selection for prediction models and increase the spatial-temporal extent of such predictions by using geostatistical interpolation techniques. These modeling efforts will culminate in a prediction tool that will provide real-time forecasts of *V. parahaemolyticus*. These prediction models will better inform shellfish harvesters and regulators on when and where preventative food safety post-harvesting practices are necessary.

### **P03.0150. Air Quality Related Health Co-Benefits of Mitigating Climate Change in South Korea**

Satbyul Kim

*Satbyul E. Kim<sup>1</sup>*

*1. National Institute for Environmental Studies, Tsukuba, Ibaraki, Japan.*

**Abstract:** Climate mitigation reduces fossil fuel consumptions and greenhouse gas emissions, which generally contribute to the reduction of air pollutant emissions. Bad air quality poses a threat to human health (mortality and morbidity), increases medical expenditure, and decreases labour supply. This study aims to quantify health co-benefits for air pollution reduction scenarios due to climate mitigation in both physical and monetary terms in South Korea. We used an integrated approach to consider an air quality model, a health assessment model, and an economic model to evaluate the long-term health and economic impacts caused by air pollution (PM<sub>2.5</sub> and ozone) under climate mitigation scenario and SSPs in South Korea. Climate mitigation towards 3.4 W/m<sup>2</sup> reduces 0.02 (95% C.I.: 0.01-0.04) million premature death under SSP2 in 2050 compared with reference year of 2005. Medical expenditure expected to be increased due to GDP escalation, amount of increase is 0.17 billion USD under SSP2, and 0.35 billion USD under SSP3. Work loss hours expected to be decreased by 3.19 hours per capita under SSP2 scenario. Net benefit of climate mitigation is more than 20 billion USD. Improved air quality could provide significant health benefits in near future.

**P03.0160. Nationwide Epidemiological Study of Stroke Occurrence and Temperature in China: Association, Susceptibility and Risk Burden**

Tianjia Guan

*Tianjia Guan<sup>1</sup>, Tao Xue<sup>2</sup>, Yuanli Liu<sup>1</sup>, Tong Zhu<sup>2</sup>*

*1. School of Public Health, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China.*

*2. Peking University, Beijing, China.*

Abstract: Stroke, a leading issue of public health has been linked to outdoor temperature. However, the association has been rarely examined by nation-scale study in China. Making use of 11,144 stroke (including ischemic and hemorrhagic stroke) or transient ischemic attack (TIA) patients from 339 communities and temperature estimates from an assimilation of in-situ observations, satellite measurements and simulates of Weather Research Forecast model, we conducted a case-crossover study during 2000-2016. Occurrence of stroke or TIA was associated to temperature anomaly by a lag-distributed nonlinear model. The variations of the association were further explored by strata of subpopulations and by geographic regions. Attributable fraction was finally derived to quantify risk burden of stroke. Either ischemic or hemorrhagic stroke was strongly associated to both cold or heat temperature at different lags, while TIA was weakly linked to cold weather at lag 0 day. During lag 0-2 day, the risk of stroke increased by 20% (95% confidence interval: 3%, 40%) for extreme cold or 19% (3%, 37%) for extreme heat. We also found that re-occurred stroke was more strongly associated to temperature than first stroke. In China, irregular variation of temperature might attributed 3.42% of stroke attacks. More stroke occurrences were attributed to heat (2.05%) than cold (1.38%). During 2000-2016, stroke risk was estimated to increase by 0.02% per year with the changed temperature, particularly the increment of heat events. Our findings enrich epidemiological evidences on the association between stroke and temperature, and support China's policymakers to plan stroke prevention and climate change mitigation.

### **P03.0170. Daily Ambient Temperature Is Associated with Biomarkers of Kidney Injury in Older Americans**

Trenton Honda

*Trenton Honda<sup>1</sup>, Justin Manjourides<sup>1</sup>, Helen Suh<sup>2</sup>*

*1. Northeastern University, Mansfield, MA, United States.*

*2. Tufts University, Boston, MA, United States.*

**Abstract:** **INTRODUCTION:** Increases in ambient temperature have recently been associated with increased risk of hospital admission for a number of kidney pathologies. However, how increased temperature might affect renal pathophysiology has not yet been elucidated. **METHODS:** Multiple regression models evaluated the association between 1- and 3-day average, ambient temperature levels and biomarkers of kidney injury (neutrophil gelatinase-associated lipocalin (NGAL) and adiponectin), among 3,377 individuals over 57 years of age enrolled in the National Social Life, Health, and Aging Project. Mediation of the affects of temperature through blood pressure was also explored. Temperature estimates were based upon data from the National Climatic Data Center (NCDC) and spatially smoothed on a six-kilometer grid covering the U.S.. Models were adjusted for demographic, socioeconomic, health behavior, medical history variables, and ambient particulate matter. **RESULTS:** Individuals in the top quartile of daily temperature (>200C) had 16.10% (SE 5.70%, p=0.008) higher levels of NGAL and 28.03% (SE 6.35%, P<0.001) higher levels of adiponectin relative to those in the lower quartiles. Associations for 3-day average exposures were attenuated (NGAL: 9.90%, SE 5.61, p=0.086; Adiponectin: 20.96%, SE 6.28%, p=0.002). Spline curves of continuous temperature exposures identified significant non-linearity, with non-significant associations for ambient temperatures <100 C, and significant, linear effects for ambient temperatures ≥100C. In models restricted to exposures ≥100C, each 10C increase was associated with 1.98% (SE 0.58, p<0.001) higher NGAL and 2.77% (SE 0.63, p<0.001) higher adiponectin levels. Significant mediation was not identified. **CONCLUSIONS:** In a cohort of older Americans, daily ambient temperature exposures were significantly associated with biomarkers of acute renal injury. These associations suggest that ambient temperature exposures may be an important risk factor for acute kidney injury.

### **P03.0180. Sex as Effect Modifier of the Association between Daily Wet-Bulb Temperatures and Kidney Stones Presentations**

Ana Vicedo-Cabrera

Ana M. Vicedo-Cabrera<sup>1</sup>, Robert E. Kopp<sup>2</sup>, Lihai Song<sup>3</sup>, David S. Goldfarb<sup>4</sup>, Michelle Ross<sup>5</sup>, Jose Pulido<sup>6</sup>, Gregory E. Tasian<sup>3</sup>

5. *Department of Biostatistics and Epidemiology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, United States.*
6. *Department of Surgery, Division of Urology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, United States.*

**Abstract:** Background and aim: Compared to female mammals, males have greater evaporative water loss and renal water reabsorption, which affects urine volume, a determinant of kidney stone formation. In this contribution, we assessed whether sex modifies the relationship between temperature and emergent presentations for kidney stones. Methods: We collected data from 132,597 individuals who presented with kidney stones to 68 emergency departments throughout South Carolina from 1997 to 2015. Daily weather variables at ZIP code level were collected through NASA Land Data Assimilation Systems. We performed an aggregated case-crossover study at zip code level, applying distributed lag nonlinear models to explore the non-linear and lagged association between daily kidney stones presentations and maximum daily wet-bulb temperatures over 10-days. We assessed effect modification through interaction terms between sex indicator and the cross-basis term of maximum daily wet-bulb temperatures. We also explored interactions by other individual characteristics such as age, race, payer status, and climate. Results: Compared to 10°C, daily wet-bulb temperatures at the 99th percentile were associated with a 73% increased risk of kidney stone presentations among males (95% confidence interval: 1.56-1.91) and a 15% increased risk among females (1.01-1.32; interaction  $p < 0.001$ ). There were weak differences by age, race, and climate that were not statistically significant, and no differences between private versus public insurance. Conclusion: Our results suggest a greater risk of presenting kidney stones in males after the exposure to extremely high temperatures. These findings have implications for clarifying the impact of climate change on human health and suggest that strategies to mitigate the effect of high temperatures may produce the greatest public health benefit for men at risk for kidney stone presentation.

### **P03.0210. Health Co-Benefits and Impacts of Transitioning from Fossil-Fuel Based to Cleaner Energy Sources in Higher-Income Countries: What Do We Know?**

Rachel Tham

*Rachel Tham<sup>1</sup>, Gayan Bowatte<sup>2</sup>, Shyamali Dharmage<sup>1</sup>, Geoffrey Morgan<sup>3</sup>, Guy Marks<sup>4</sup>, Christine Cowie<sup>4</sup>*

- 1. Epidemiology and Biostatistics, University of Melbourne, Melbourne, VIC, Australia.*
- 2. National Institute of Fundamental Studies, Kandy, Sri Lanka.*
- 3. School of Public Health, University of Sydney, Lismore, NSW, Australia.*
- 4. South West Sydney Clinical School, University of New South Wales, Sydney, NSW, Australia.*

**Abstract:** Background: It is hypothesised that transitioning from traditional fossil fuel use to cleaner energy sources will have significant environmental benefits and health co-benefits related to reduced air pollution. However, little is understood with regard to potential adverse health impacts of new energy forms. Aim: To systematically synthesise current research that examined shifts to cleaner energy sources with specific consideration of health co-benefits. Method: Systematic search of PubMed, Medline and EMBASE databases and hand-searching for peer-reviewed studies published in English to 24 January 2018. Inclusion criteria: energy use or energy transition related to health outcomes or co-benefits; epidemiological, health impact assessment, modelling or hypothesised. Results: Of 5031 articles found, 58 original research and 14 review papers were considered. Few papers explicitly considered health benefits of energy transitions other than climate change scenarios. Papers were in key areas: biofuels; photovoltaic (PV) cells (solar panels); wind turbines; electrification of vehicles; modelling climate change policies; increased or decreased energy consumption and improved air quality; econometric modelling; and improved residential energy efficiency. Key findings were 1) biofuels, electric cars, PV cells and wind turbines may produce lower levels of air pollutants but there may be health risks associated with their production, use or disposal that needs to be incorporated in the overall assessment of health effects; and 2) environmental justice issues arise when an inequitable health burden is placed on poorer communities living near sites of electricity production while wealthier sectors benefit from newer technologies which are currently expensive e.g. electric vehicles. Conclusion: The degree of health benefit varies with the energy technology type. There is a need for targeted health impact assessments that incorporate life cycle assessment of newer energy technologies.
